Show me the Money: Federal R&D Support for Academic Chemistry, 1990–2009

Abstract

We examine the distribution of Federal support for chemistry Research and Development (R&D) performed at U.S. universities from 1990-2009. Federal R&D funding is an essential source of funds for investigator-driven research at the nation's universities. Previous studies have documented that aggregated federal R&D funding has become more dispersed over time and attributed this to political pressure to spread resources more evenly. There have, however, been few studies of the allocation of funds within narrowly defined scientific disciplines. By narrowing the focus and exploiting the panel nature of our data we are better able to analyze the correlates of funding variation, yielding a number of new insights not apparent in studies using more aggregated data. First, we find that R&D expenditures at the discipline level are considerably more volatile than aggregate funding. Second, we show a strong positive association between several measures of institutional research capacity and future funding. In particular, we find a positive association between the employment of postdoctoral researchers and higher future research funding.

ABSTRACT

We examine the distribution of Federal support for chemistry Research and Development (R&D) performed at U.S. universities from 1990-2009. Federal R&D funding is an essential source of funds for investigator-driven research at the nation's universities. Previous studies have documented that aggregated federal R&D funding has become more dispersed over time and attributed this to political pressure to spread resources more evenly. There have, however, been few studies of the allocation of funds within narrowly defined scientific disciplines. By narrowing the focus and exploiting the panel nature of our data we are better able to analyze the correlates of funding variation, yielding a number of new insights not apparent in studies using more aggregated data. First, we find that R&D expenditures at the discipline level are considerably more volatile than aggregate funding. Second, we show a strong positive association between several measures of institutional research capacity and future funding. In particular, we find a positive association between the employment of postdoctoral researchers and higher future research funding.

Acknowledgements

The research reported here was supported in part by the National Science Foundation's Science of Science and Innovation Policy Program under award 1064218. We have benefited from the insightful comments of Irwin Feller, David Popp, Otavio Bartalotti and participants in the Iowa State University "no free lunch" colloquium, and express our appreciation for their assistance. Needless to say, any remaining errors are the responsibility of the authors.

1. Introduction

Ask any university scientist about the importance of external research funding and she will tell you that it is essential to supporting her laboratory. Without funding it would not be possible to get the research done; there would be no money to pay for supplies or hire the graduate students and postdocs essential to conducting the experiments. One illustration of the importance of funding for the research enterprise is provided by a survey we recently conducted of academic chemists in the United States. In that survey we asked how a 25 percent reduction in funding would affect their research activities; over 75 percent of respondents said lower funding would result in fewer publications, 81 percent said they would be able to support fewer graduate students, 68 percent said they would employ fewer postdocs and 40 percent said that they would generate fewer patents.¹

While universities typically provide new faculty with substantial “start-up” packages to establish a research program, the ability of faculty to attract and retain sponsored research funds has become an essential criterion in promotion and tenure decisions. At the department and university level, the volume of sponsored research performed has emerged as an increasingly important factor in institutional ranking, figuring heavily in the National Research Council’s evaluation of graduate programs as well as lists produced by popular publications. In the United States, the release each year of the National Science Foundation’s Higher Education Research & Development survey results showing sponsored research funding is widely

¹ The survey was conducted during the Spring of 2014. Email invitations to participate in an online survey were sent to all faculty in the United States with valid email addresses listed in the American Chemical Society’s *Directory of Graduate Research* for 2013. Invitations were sent to 7,438 individuals and we received 1,544 completed survey responses.

publicized by institutions that have moved up and downplayed by those who have fallen in their rankings.

Attracting research funding is important for university leaders not only because it signals the reputation and prestige of their faculty, but because this support typically includes payments for research overhead costs that cannot be allocated to specific research projects. These payments for “Facilities and Administration” (F&A) costs are commonly in the range of 50% or more of the direct costs of the research being performed. For public institutions grappling with shrinking state appropriations and private institutions seeking to control the growth of tuition, this stream of funding has become an increasingly important source of funds. Collectively the nation’s universities advocate for expansion of the federal research budget, while individually they are all seeking to capture a larger slice of the pie and move up in the rankings.

Funding also matters for the production of new scientific knowledge. There is, by now, an extensive literature that seeks to measure the impacts of R&D funding on scientific outputs. Much of this literature relies on cross-sectional variations in funding across individuals or institutions or times-series variation to draw inferences about the marginal impact of additional funding on the production of articles, patents or other measures of scientific productivity.² Teasing out the causal effects of funding on publications is challenging, but a number of studies have concluded that additional funding does have a positive impact on rates of publication

²Typically these studies have used some combination of publications, citations to publication or patents as their indicator of scientific production. See for example, Adams and Griliches (1998); Arora, and Gambardella (2005); Blume-Kohout, Kumar, and Sood (2013); Jacob and Lefgren (2011) Payne and Siow (2003), Rosenbloom et al (2015); Whalley and Hicks (2014); Popp (2015). For a somewhat less econometric perspective, see Moffitt (2016).

(e.g., Payne and Siow 2003; Jacob and Lefgren 2011; Popp 2015; Rosenbloom et al 2015).

Whatever the marginal effects of variation in funding, there can be little doubt that in the aggregate federal R&D funding is an important source of support for the nation's scientific enterprise.

Despite the importance of federal funding for scientific R&D, the factors that influence the distribution of federal R&D funding have not been subjected to the same detailed examination as the impacts of this funding. One could argue that this topic has not previously been studied because the allocation of funding is simply an intermediate step in the production of new scientific knowledge that does not merit close attention. There are, however, several a priori arguments for looking at the allocation of funding. Moreover, as this article shows, such an examination yields a number of useful empirical insights about science funding that should inform federal science policy.

While it is true that the ultimate goal of federal support for basic research is to advance the frontiers of knowledge, the allocation of federal R&D funds has important implications for higher education institutions. Grant funds provide much of the support for the training of doctoral and post-doctoral scholars, so the way in which funds are allocated plays an important role in determining where the next generation of scholars will be educated. At the same time, the linkage between F&A payments and the direct costs of science means that the allocation of funds has implications for the support of scientific infrastructure. Together these factors

influence institutional reputations and resources that affect faculty recruiting, and shape the structure of the higher education enterprise.³

The higher education landscape is quite diversified, including institutions with very different missions. Most research activity is concentrated in a few hundred doctoral degree-granting institutions. But these institutions include both publicly supported and private institutions of quite different scales and research intensity. In the 1950s and 1960s, as a result of federal investments in science after Sputnik, the group of research universities expanded significantly (Graham and Diamond 1997, ch. 2). Since the mid-1970s, however, as the growth of federal R&D funding slowed, the group of research universities has more or less stabilized, and competition between them to move up the rankings has intensified. Thus a central empirical question to be answered here hinges on whether there are systematic advantages associated with university size, research intensity or control that, other things equal, affect the distribution of research funds.

The premise of the merit-review process used by the National Science Foundation (NSF), the National Institutes of Health (NIH) and other federal agencies is that funding should be allocated to support the best science as judged by other scientists. Yet the primacy of merit review has not fully insulated science funding from the pressure of members of Congress seeking to steer more federal science funds to their own districts. These pressures are manifested both in earmarks for certain projects and in programs like NSF's Experimental Program to Stimulate Competitive Research (EPSCoR) and NIH's Institutional Development

³ Research universities are themselves sources of local economic development spillovers. As attention to the innovation systems that have emerged in Silicon Valley, Route 128 around Boston, the Research Triangle and in Austin, Texas suggests, fostering robust university research enterprises is seen as one key to innovation-led economic growth strategies.

Award (IDeA) Program, both of which target funding to scientists in states receiving disproportionately low levels of funding.

Feller (2001) provides a good summary of what might be described as the political economy of federal science funding. As he notes, there is a tension between supporting scientific excellence, which channels funds to elite institutions, and insuring a more equitable distribution of funding across states. Over the years a number of studies have tracked aggregate levels of Federal R&D funding across institutions or states (Geiger and Feller 1995; Graham and Diamond 1997; Feller 2001) focusing primarily on the relative proportion of federal funds in comparison to other measures of scientific capacity. These studies have typically concluded that since the 1960s, funding has tended to become more dispersed and has contributed to the expansion of the nation's research capacity beyond the small group of elite universities that dominated research and graduate training in the 1950s.

In addition to this work there have also been some studies that explored the interactions between federal and non-federal sources of funding. Mostly this research has been motivated by the question of whether federal funding is a substitute or complement for non-federal funding. Using somewhat different approaches Blume-Kohout, Kumar and Sood (2013), Payne (2001), and Lanahan et al (2016) have all concluded that increased federal funding tends to increase research expenditures from other sources rather than crowding them out.⁴ Ehrenberg, Rizzo and Jakubson (2003) have pointed out that in aggregate, since the 1980s the share of university research expenses supported by federal funds has declined, dropping from over 60% to under 55%. Analyzing panel data for 228 universities, they conclude that

⁴ David, Hall, and Toole (2000) survey the literature on the relationship between federal and industrial R&D spending.

universities have responded to the falling levels of federal support by reducing faculty-student ratios, and increasing tuition, in effect subsidizing research expenditures by increasing the costs and reducing the quality of instruction.

Aggregate descriptions of the sort noted above are helpful in sketching the broad outlines of federal research support, but because they combine data on funding across a broad range of scientific disciplines they cannot yield much insight about the factors influencing the patterns that they describe. Wachtel (2000) has analyzed the distribution of the National Science Foundation's funding of economics research. Noting that funding is highly concentrated among a small group of the discipline's top departments, which also provide many of the reviewers who advise on funding decisions, he argues that funding decisions are not being made objectively. Wachtel's argument is largely circumstantial, resting on the coincidence of institutional affiliations of reviewers and grant recipients, and does not control in any way for the quality of projects being proposed. With access to NSF administrative data for all proposals made to the NSF Economics Program from 1996 to 2000 Feinberg and Price (2004) were able to provide a more nuanced analysis. Controlling for race, ethnicity, gender, and the institution where applicants are employed they were able to account for a number of likely correlates of quality. Even after including all of these controls, however, they found that researchers affiliated with the National Bureau of Economic Research (NBER) were more likely to receive funding than otherwise comparable applicants not affiliated with NBER.

Focusing at the level of individual investigators, Ginther et. al. (2011, 2012, 2016) examined race/ethnicity and gender differences in the probability of receiving NIH funding. After controlling for several individual and institutional covariates, these studies found that the

NIH funding rank of the institution was associated with a higher probability of funding. In other words, the wealthier the institution in terms of NIH funding, the more likely a proposal from an investigator affiliated with that institution was to receive funding. However, these studies do not control for the fact that the best researchers are more likely to be employed by the best-funded institutions.

With the exception of these few studies, we are not aware of other work that has sought to analyze the distribution of federal R&D funding within a single scientific discipline. If we are going to gain greater insight about the factors that influence the allocation of funding, however, it is necessary to study funding at this more disaggregated disciplinary level. In what follows we begin such an analysis focusing on federal R&D funding in Chemistry between 1990 and 2009. By limiting the scope of our analysis to a single discipline we are able to consider more explicitly the extent to which measures of institutional quality affect funding.

We begin in the next section by describing in more detail the data that we use, and present a number of summary and descriptive statistics. We show that federal support for chemistry research is quite unevenly distributed across universities and that the overall size distribution of funding has remained stable over time. Looking at the performance of individual institutions, however, belies the initial impression of stability. The fortunes of particular universities have changed quite a bit since the early 1990s. In section 3, we introduce a dynamic panel regression framework to more systematically analyze the determinants of funding at the university level. This analysis points to several important conclusions. First, we find evidence that levels of funding are positively related to past research output. Second, we find that, an increase in the number of postdoctoral scholars employed is associated with

higher levels of federal funding. Third, we find a positive association between non-federal research funding levels and federal R&D funding, consistent with the complementarity between these funding sources found by Blume-Kohout, Kumar and Sood (2013) and Payne (2001). On the whole these results suggest that institutional capacity is an important determinant of funding.

2. An Overview of the Research Funding Landscape for Academic Chemistry

To conduct our analysis, we have gathered annual data on federally funded and total academic chemistry and chemical engineering (for brevity we will refer to these combined fields as chemistry) R&D expenditures at U.S. universities and colleges between 1990 and 2009 from NSF's Higher Education Research and Development (HERD) survey.⁵ We link these to data on publications and citations to those publications derived from Thomson Reuters Web of Science database, counts of doctorates awarded and postdoctoral scholars from the NSF-NIH survey of Graduate Students and Postdoctorates, and faculty counts that we hand collected from directories published by the American Chemical Society. Additional details concerning data sources and how we linked them are contained in the Data Appendix. We chose to focus on academic chemistry because it is well established, widely represented across the universe

⁵ Although ideally one might want to analyze chemistry and chemical engineering separately, differences in the way disciplines are defined across our different data sources make it necessary to aggregate the two distinct fields. To illustrate this point, of the 150 institutions we initially examined, there were 102 that had chemical engineering departments that reported faculty numbers in the American Chemical Society directory and 48 that did not. However, only 22 institutions reported zero amounts of federally funded R&D expenditures for chemical engineering research in every year, and there are no institutions for which Web of Science recorded zero chemical engineering publications in all years. The mismatch in classification across the different sources used in our analysis suggests that attempting to analyze these fields separately would likely cause more problems than it solves.

of higher education institutions, and accounts for a significant share (about 4%) of federally funded academic R&D.

Our analysis sample consists of the 147 institutions with the highest aggregate value of real federally financed academic chemistry R&D expenditures over the 20-year period from 1990 to 2009. We initially focused on the top 150 institutions, but were subsequently obliged to drop three of them because the available data were incomplete or appeared inconsistent.⁶ In aggregate our sample accounted for over 90% of federally supported and total chemistry R&D expenditures in each year, produced more than 90 percent of research doctorates earned in chemistry annually and employed almost 95% of the postdoctoral researchers. The institutions in our sample also represent a highly diverse population ranging from chemistry powerhouses such as MIT, which averaged close to \$37 million (in constant 2005 prices) in total chemistry R&D expenditures annually, to Cleveland State University, which averaged under \$1.2 million in chemistry R&D expenditures in the same period.

Table 1 lists the 147 institutions in our sample, ranked from highest to lowest in total real federally financed chemistry R&D expenditures over the entire twenty-year period 1990-2009. The table also reports average federally financed R&D expenditures for 5 year periods. It is apparent that funds are distributed relatively unequally, with the top 10 institutions receiving approximately 20% of funds in each period, and the top 20 accounting for more than one-third of total funding. In Figure 1 we have plotted Lorenz curves illustrating the distribution of

⁶ The three institutions dropped from our sample included two academic medical centers: the University of California San Francisco and the University of Texas M.D. Anderson Cancer Center—which reported no chemistry faculty, graduate students or postdocs for much of the study period—and the Oregon Institute of Science and Technology, which disappears from the HERD data after 2001.

Federal R&D Expenditures in 5 year periods from 1990 through 2009. Were funds equally distributed the plot would lie along the 45-degree line, which is also graphed for reference. Reflecting the concentration of funding at a relatively small number of institutions each of the plots lies well below the 45 degree line. Although the magnitude of the changes does not appear to be too great, there has been a small tendency toward an increase in the levels of R&D expenditures at institutions in the middle of the distribution over the period we are considering.

The stability of the overall distribution of funding conceals, however, a much more dynamic pattern of funding at individual institutions. The last two columns of Table 1 report the highest and lowest ordinal rankings of each institution in annual R&D expenditures over the period 1990-2009. Over the 20 years covered by our data, many institutions moved up or down by as much as 10 or 20 places in the rankings. The extent of this temporal variation is illustrated in Figure 2, which plots 5-year average expenditures (measured in constant 2005 dollars) at each institution against its rank in the 1990-1994 period. The blue dots, plotting the 1990-1994 average values follow a steadily declining gradient, but there is considerable dispersion in values around this line as time progresses. Rising levels of federal funding for chemistry R&D mean that the overall tendency is for expenditures to move up, but there are a substantial number of institutions that experienced declines in federal R&D funding, and even among those that experienced increases in funding the magnitude of increases varied considerably over time. In the next section we turn to the question of what factors have driven the varying fortunes of different universities in securing federal funding for their research activities.

3. Modeling the Distribution of Federal Funding

There are at least 14 different federal agencies that support some extramural R&D. However, the primary federal sources of funding for university research are the National Institutes of Health (NIH) and the National Science Foundation (NSF).⁷ At both of these agencies funding is distributed through a number of different mechanisms, but the dominant paradigm is to fund investigator-driven projects that are evaluated largely on their scientific merit. Both agencies rely heavily on the judgment of university scientists to assess the strengths of the proposals they receive. At the National Science Foundation, proposed research projects are evaluated based on the criteria of intellectual merit and broader impacts of the proposed activity. Although the terminology NIH uses to articulate its criteria—significance, approach, innovation, investigator qualifications, and environment—is somewhat different from that used by NSF, the two agencies are, as Gans and Murray observe (2012, p. 61) “...strikingly similar...” in the qualities that they seek to emphasize.

While both NSF and NIH selection processes are fundamentally forward-looking, in the sense that they emphasize the potential significance of the activities that are proposed, they also give weight to the qualifications of the investigators to successfully carry out the proposed research and to institutional characteristics, such as the presence of specialized facilities that may be necessary to conduct the research. As a result, past performance and institutional identity are likely to have an important influence on the allocation of funds.

⁷ See Gans and Murray (2012) for a detailed discussion of the range and objectives of federal extramural R&D funding.

To investigate how these factors affect the allocation of funding we postulate a model of the determinants of federally financed R&D expenditures, which we denote as r , at institution i in year t as:

$$(1) \quad r_{it} = f(X_{it-1}, \alpha_i, \beta_t; \varepsilon_{it})$$

where X is a vector of time and institution varying characteristics, α captures any fixed institution-specific effects on funding such as specialized facilities or institutional reputation, β is a year effect that captures common temporal shocks to funding, and ε is a stochastic error term. The variables in X are lagged one year, to reflect the fact that expenditures in t are determined by the success of past funding applications, so it is characteristics in the previous period that will affect available funding. Among the time-varying institutional characteristics we are able to measure and include in X are the number of chemistry faculty affiliated with the institution, the number of publications by faculty affiliated with each institution, citations to those publications in a three-year window following publication, the numbers of postdoctoral researchers employed, the number of doctorates awarded in chemistry and the value of non-federally funded R&D expenditures.

Holding the number of faculty constant, we expect that higher rates of publication, and greater numbers of citations per publication should signal more productive researchers, and hence be associated with greater success in attracting Federal R&D funding. Doctorates awarded and postdoctoral researchers employed at an institution might affect funding through several different pathways. On the one hand, they may be viewed as additional measures of the scientific output of that institution, since the training of graduate students and postdoctoral researchers is another way in which chemical knowledge may be transmitted. Like publications

then, they would be an indicator of higher quality faculty, and consequently would be associated with higher levels of funding. On the other hand, because graduate students and postdocs do much of the work involved in producing knowledge they are an important input in the knowledge production process. As such, they are also an indicator of institutional capacity that should be associated with greater success in attracting federal funding.

Non-federal R&D funding might either be a complement to or substitute for federal funding. If higher levels of non-federal funding increase scientific capacity and signal higher faculty quality, then they should act as a complement, inducing additional federal support. On the other hand, the availability of non-federal funds may substitute for federal support, reducing the volume of research proposals submitted by an institution or discouraging agencies from awarding funds, in which case we would expect a negative effect on federal R&D funding.

In Table 2 we report sample means for federally funded R&D and for each of the institutional characteristics in our data for the full sample, and for various subsets of institutions. As we might expect institutions in the Carnegie Research I category have higher levels of chemistry R&D expenditures, employ more faculty and postdoctoral researchers, and produce more publications and doctoral degrees than do the non-Research I institutions. It is also notable that the average number of citations to articles published by the Research I institutions is higher than for the non-Research I universities. To the extent that the number of citations an article receives is a reflection of its quality or impact, the data in Table 2 also indicate that private universities produce higher quality publications than do public universities.

Because most federal grants are awarded for periods of anywhere from 3 to 5 years these is likely to be considerable serial correlation in institutional expenditures between

successive years. Taking account of the these lags, and assuming a linear approximation to equation (1) our estimating equation becomes:

$$(2) \quad r_{it} = \alpha_i + \beta_t + \gamma_1 r_{it-1} + \gamma_2 r_{it-2} + \sum \delta X_{it-1} + \varepsilon_{it}$$

Because of the autoregressive nature of this relationship, conventional approaches to fixed effects panel estimation are no longer appropriate (Cameron and Trivedi 2010, p. 293-94).

Instead it is necessary to deal with fixed effects by estimate the relationship in first difference form:

$$(3) \quad \Delta r_{it} = \Delta \beta_t + \gamma_1 \Delta r_{it-1} + \gamma_2 \Delta r_{it-2} + \sum \gamma \Delta X_{it-1} + \Delta \varepsilon_{it}$$

Institution fixed effects can be removed by first differencing, but differencing means that the lagged dependent variable can no longer be regarded as exogenous. A number of approaches have been suggested for estimating the autoregressive relationship using instrumental variables. The most widely used approach, proposed by Arellano and Bond (1991), uses longer lags of the dependent variable as instruments. We use the XTABOND procedure in STATA 14 to estimate dynamic panel regressions of equation (3).⁸ The results are reported in Table 3 for a variety of different combinations of the explanatory variables. Although the equation is estimated in first differences, STATA transforms the results to show the coefficients for the original specification in levels. Consistent with the expected serial correlation of R&D expenditures we find that in all cases the first lag of the dependent variable exerts a large and

⁸ For long panels the number of potential instruments available for the lagged dependent variable can become quite large. With the inclusion of two lags of the dependent variable among the regressors there would be two available instruments at t=4, three at t=5, and 18 at t=20. After some experimentation we opted to limit the number of instruments to a maximum of 5. Results are not sensitive, however, to changes in this maximum.

statistically significant effect. The coefficient on the second lag is smaller in magnitude and negative.

As we have noted earlier, the number of faculty at a university is our primary scale variable. To control for differences in quality of research ideas and the qualifications of the investigators we include the number of scientific publications as well as the average number of citations that those publications received in a three-year window following their publication. The latter measure can be interpreted as adjusting the volume of publication for the overall impact that these publications may have had.⁹ As we noted, earlier, the number of doctorates awarded and the number of postdoctoral researchers employed can be viewed either as additional measures of institutional quality or as a measure of institutional capacity, augmenting faculty as a measure of scale. Finally, we include the amount of non-federally funded chemistry R&D expenditures. This variable will reflect both the commitment of institutional funds to support research and the role of industrial and state level support. Because there are a number of zero values among the right hand side variables we estimate the equation in levels rather than logs.

In the first 6 columns we add progressively more explanatory variables until we have included all of the hypothesized determinants of funding. Column 7 drops the measures of faculty, postdoctoral scholars, and doctorates awarded as a test of the stability of the coefficient estimates for the remaining variables. Coefficient estimates for most of the variables are quite stable across different specifications of the model, and imply that lagged

⁹ The number of citations received is measured over a three year window following publication, so this number would not be known to reviewers involved in the merit review process. Rather it is an indicator of the importance of the articles that these reviewers might infer from other sources.

values of both the number of publications and the number of postdoctoral scholars are associated with economically large and statistically significant increases in federally funded R&D. Lagged non-federally funded R&D expenditures also have a positive effect on future federally funded R&D, but this effect is not consistently statistically significant. For consistent estimation, the Arellano-Bond estimation procedure requires that the errors, ε_{it} , be serially uncorrelated beyond order 1. This assumption can be tested using the fitted residuals (Cameron and Trivedi 2010, p. 300). At the bottom of the table we report the Z-statistic for the test of this hypothesis along the probability of obtaining a value at least this big. We do not reject the hypothesis of zero autocorrelation for any of our models.

Given the stability of the coefficient estimates across different specifications, we prefer specification (6), which includes the richest set of explanatory variables. Since the dependent variable, federally funded R&D, is measured in \$1000s, our preferred specification implies that there is a strong, positive, and statistically and economically significant effect from the number of postdoctoral scholars employed in the previous year: each additional postdoctoral scholar is associated with an increase in federal funding of approximately \$10,000 in the subsequent year (an implied elasticity of 0.05). Each additional publication in the previous year is associated with close to \$4,000 in additional federally funded R&D; evaluated at the sample mean this implies an elasticity of funding with respect to publications of 0.1. There is also a small, positive and sometimes statistically significant effect of non-federally funded expenditures on federal funding; the coefficient estimates in column (6) imply that each additional \$1000 of non-federal expenditures is associated with about \$54 dollars of additional federal funding (an elasticity 0.03 at the sample means).

One concern with the estimates reported in Table 3 is the possibility that the positive relationship between funding and the number of postdocs arises because of potential endogeneity. Because postdocs are typically hired for several years, it is possible that a shock to funding in year $t-1$ might increase both the number of postdocs employed in year $t-1$ and volume of research expenditures in year t . We address this possibility by instrumenting for postdocs using additional lags of the postdoc variable. Table 4 compares IV estimates with our baseline estimates. In the three different IV specifications we report we use different numbers of lags as IV, experimenting with 3, 5 and 10 lagged values of postdocs as instruments. Point estimates of the coefficients are relatively stable regardless of the number of instruments, but the magnitude of the effect of postdoctoral scholars increases with more instruments. With fewer IVs this effect is not statistically significant, but as when we use 10 lags of the variable it becomes statistically significant at the 10 percent level.

Another important question concerns the stability of the relationship between measures of research quality and capacity across different subgroups of universities. In Table 5 we re-estimate equation (3) separately for subsamples of institutions, focusing on our preferred specification that includes all of the explanatory variables. Column 1 reproduces our earlier estimates for the full sample for comparison. Columns 2 and 3 report results separately for public and private universities, while Columns 4 and 5 show separate regression for institutions classified as Carnegie Research I and not Research I. The estimates for non-Research I universities reported in Column 4a violate the assumption of zero autocorrelation of the residuals at order 2. The solution to this problem is to add additional lags of the dependent variable until the assumption is satisfied. In Column 4b we show that after including a third lag

of funding this assumption is satisfied. This modification does not, however, greatly affect any of the other estimated coefficients.

With the smaller sample sizes the precision of many of the point estimates falls. Among private universities, we find a much smaller effect of variations in the number of postdoctoral scholars and non-federally funded expenditures, while the effect of past publications emerges as a much stronger factor in the distribution of funding. Among public universities this pattern is reversed, with the number of postdoctoral scholars and non-federal funding exerting a larger influence, while variations in publication rates appear to have no effect. When the sample is split by research intensity, we find that none of the explanatory variables have a statistically significant effect on funding among the non-Research I institutions, while the magnitudes of the effects for the more research intensive, Research I, universities closely resemble those estimated for the full sample.

4. Discussion

We began this investigation by noting that federal R&D funding for chemistry research is distributed unequally across universities and that over time levels of funding at individual universities vary quite a bit. One interpretation of variations in funding levels is that they respond to variations in the scientific merit of research proposals submitted by investigators at these different institutions. An alternative is that the distribution of funds reflects either political pressures to distribute funds more equitably across political jurisdictions or that favoritism among those making allocation decisions leads to the concentration of funds in the hands of a favored few.

These explanations are not mutually exclusive. They may both operate to varying degrees simultaneously. However, the results reported in the preceding section confirm the important role that scientific merit plays in the allocation of funds. Institutional characteristics that are associated with more productive faculty and a greater capacity to conduct chemistry research – past publications, the number of postdoctoral scholars employed, non-federally funded R&D expenditures – are all economically significantly associated with higher levels of funding.

The effect of postdocs on research funding is rather striking, especially since neither measures of the number of graduate students nor faculty are associated with an increase in federal funding. The National Institutes of Health (NIH) and the National Science Foundation (NSF) define the postdoctoral scholar to be “individuals engaged in temporary periods of mentored advanced training to enhance the professional skills and research independence needed to pursue their chosen career paths.”¹⁰ However, the postdoc is controversial, and some have labeled the postdoc as “exploitation” given the low salaries, lack of benefits, and high rates of foregone earnings (Stephan 2013, Kahn and Ginther (2017). Stephan (2013) argued that the postdocs persists because faculty can hire inexpensive and temporary employees to conduct research. Our analysis provides the university’s rationale for postdoctoral scholars: postdocs increase the future stream of research funding flowing to the university.

For public university leaders seeking to increase their share of the federal R&D pie, our results suggest that increasing the number of postdoctoral fellows and greater investments of

¹⁰ http://grants.nih.gov/training/Reed_Letter.pdf

non-federal funding for R&D will increase competitiveness. Correlation is not, of course, the same as causation. Our dynamic panel estimates account for a number of potential sources of reverse causation. In the absence of truly experimental variation or sources of large exogenous shocks, however, it is difficult to argue that we have isolated truly causal relationships. Nonetheless, our results suggest that such relationships exist and ought to encourage further efforts to investigate them.

5. Conclusion

This article offers an initial exploration of a topic that has so far been largely neglected in the Science of Science Policy literature: the factors influencing the allocation of federal R&D funding at the level of an individual scientific discipline. Past discussion has tended to focus on total R&D funding, an approach that makes it difficult to incorporate measures of scientific merit or scale. We have focused here on one discipline, chemistry, but believe that it would be fruitful to expand this research program to make comparisons across other disciplines. We expect that the results will likely vary, depending on disciplinary characteristics.

The results of our investigation suggest that there are a number of systematic relationships that influence variations in funding across institutions, and these correspond to factors a priori expected to be important. Numbers of postdoctoral scholars, for example are both an indicator of the human capital capacity of an institution and an important input into the preparation of competitive research funding proposals. Since postdoctoral scholars are highly dependent on external funding to cover their salaries, it makes considerable sense that institutions that have large numbers of postdoctoral scholars would attract more funding.

Similarly, given the importance of physical capital and specialized equipment the evidence that we find of positive effects of non-federally funded R&D on subsequent federal support makes a great deal of sense. Finally, given the emphasis on investigator qualifications it makes considerable sense that past publication positively affects subsequent funding. On the other hand, one might note that all of these relationships suggest mechanisms through which past success supports future success, a version of the so-called “Matthew effect, “where the rich get richer. With the available data it is not possible to tease apart these two alternative interpretations of our results. On the other hand, the relationships we find suggest a need for further investigation using higher resolution data that will enable a sharper distinction between these interpretations.

Data Appendix

Research & Development Expenditures

These data are derived from the National Science Foundation's Survey of Research and Development Expenditures at Universities and Colleges/Higher Education Research and Development Survey (<http://webcaspar.nsf.gov>). Data are available annually since 1973 for total and federally funded R&D expenditures by discipline. They are obtained from survey responses completed by institutions of higher education, which are responsible for classifying all research expenditures by discipline. We computed non-federally funded R&D expenditures as the difference between total and federally funded R&D expenditures.

Sample institutions were selected from the universe of institutions represented in this data by summing real federally funded R&D expenditures (in prices of 2005) for chemistry and chemical engineering between 1990 and 2009 and then ranking institutions in descending order. We initially selected the top 150 institutions but as described in the text were obliged to drop three of these from the analysis because of inconsistencies in coverage. Before adopting this sampling strategy, we examined several other rankings, using total R&D expenditures and using nominal rather than real expenditures. The lists produced in each case were quite similar. The full list of institutions included in the study in declining order of federally-funded chemistry R&D expenditures is provided as S1 Table.

Institutions report these data for the fiscal year corresponding most closely to the federal fiscal year. In most cases this is likely to run from July of one year to June of the following calendar year. Data are labeled with the calendar year in which the fiscal year ends. Hence data for 2009 most likely cover expenditures from July 2008 through June 2009.

In addition to the expenditures data, this source also contains information on type of control (private or public) and standardized Carnegie Classifications that we use to categorize university types.

Doctorates Awarded and Postdoctoral Researchers

These data are derived from the National Science Foundation and National Institutes of Health Survey of Graduate Students and Postdoctorates in Science and Engineering (graduate student survey) which is conducted annually by the National Center for Science and Engineering Statistics. The survey is conducted in the fall semester of each academic year and data are collected at the department level. These data are available from <http://webcaspar.nsf.gov>.

The level of institutional detail provided in this survey is greater than in the R&D expenditure data. In the latter survey a number of multi-campus state systems report a single aggregated number. To link the data sets, we were obliged to aggregate the data in the student survey to match the level of aggregation of the R&D data.

Publications and Citations

Publication and citation data were computed by Thomson Reuters, Research Analytics from the data underlying the Web of Science publication and citation database. Thomson Reuters subject area experts categorize journals into subject classes based on detailed analysis of the content and focus of the journals. See http://wokinfo.com/media/essay/journal_selection_essay-en.pdf for additional details regarding the selection process used by Thomson Reuters in compiling the Web of Science data. The Web of Science is relatively selective about which journals are included, reflecting subject

expert judgment and objective metrics of journal impact. Our research began with the full set of journals that Thomson Reuters categorizes as Chemistry and Chemical Engineering. We also conducted an analysis of all journal titles indexed by Thomson Reuters and added a small number of additional journals that contain significant chemistry content.

We then worked closely with Thomson Reuters staff to match publications by author affiliation to universities in our sample. In addition to institution name, we considered city, state and zip code information associated with authors to verify the accuracy of article linkages.

After verifying the full list of publications, Thomson Reuters analyzed them to produce summary statistics describing the number of publications each year produced by each institution, the number of citations that those publications received in 3 and 5 year windows beginning with the publication year, and a variety of other citation related metrics.

Notes to Table 3

All specifications estimated using the XTABOND procedure in STATA 14, using robust standard errors and specifying a maximum of 5 lags of the dependent variable as instruments. All regressions include year fixed effects.

* p<0.10 ** p<0.05 *** p<0.01"

Notes: All specifications estimated using the XATABOND procedure in STATA 14, using robust standard errors and specifying a maximum of 5 lags of the dependent variable as instruments. All regressions include year fixed effects. In specifications (2)-(4) Postdocs(t-1) is treated as endogenous, and instrumented with lagged values. Specifications differ only in the number of lags used. Specification (2) uses 3 lags as instruments, specification (3) uses 5 lags, and specification (4) uses 10 lags.
