Abstract

Allopolyploidization in plants entails the merger of two divergent nuclear genomes, typically with only one set (usually maternal) of parental plastidial and mitochondrial genomes and with an altered cytomolecular stoichiometry. Thus, we might expect cytomolecular coevolution to be an important dimension of allopolyploid evolution. Here, we investigate cytomolecular coordination for the key chloroplast protein rubisco (ribulose 1,5-bisphosphate carboxylase/oxygenase), which is composed of nuclear-encoded, small subunits (SSUs) and plastid-encoded, large subunits. By studying gene composition and diversity as well as gene expression in four model allopolyploid lineages, Arabidopsis, Arachis, Brassica, and Nicotiana, we demonstrate that paralogous nuclear-encoded rbcS genes within diploids are subject to homogenization via gene conversion and that such concerted evolution via gene conversion characterizes duplicated genes (homoeologs) at the polyploid level. Many gene conversions in the polyploids are intergenic with respect to the diploid progenitor genomes, occur in functional domains of the homoeologous SSUs, and are directionally biased, such that the maternal amino acid states are favored. This consistent preferential maternal-to-paternal gene conversion is mirrored at the transcriptional level, with a uniform transcriptional bias of the maternal-like rbcS homoeologs. These data, repeated among multiple diverse angiosperm genera for an important photosynthetic enzyme, suggest that cytomolecular coevolution may be mediated by intergenicomic gene conversion and altered transcription of duplicated, now homoeologous nuclear genes.

Key words: polyploid, cytomolecular coordination, rubisco, homoeologous recombination, biased expression.

Introduction

Polyploidy is a prominent evolutionary process in plants, in which two or more parental genomes are combined into the same nucleus. Through multiplying a single genome or via combining divergent genomes, autopolyploids and allopolyploids are formed, respectively (Soltis and Soltis 2000; Wendel 2000; Wendel and Doyle 2005). Although ancient polyploidy characterizes all flowering plant lineages (Jiao et al. 2011), recent allopolyploidy is observed in many plant lineages, including such well-known examples as Arabidopsis, Arachis (peanut), Brassica (cabbage), Nicotiana (tobacco), and Gossypium (cotton). In each of these genera, cytogenetic and molecular evidence have revealed extant diploid species that most closely resemble the diploid parents of the allopolyploids (Koch et al. 2000; Inaba and Nishio 2002; Chase et al. 2003; Jakobsson et al. 2006; Seijo et al. 2007; Leitch et al. 2008; Higgins et al. 2012; Bertoli et al. 2013). Comparative analyses of different allopolyploid species and their extant diploid relatives reveal that polyploidization results in complex and fascinating changes at different biological levels, including genomic alterations (loss of genes and nongenic elements and homoeologous genomic exchanges) (Lim et al. 2007; Salmon et al. 2010; Buggs et al. 2012), nonadditive gene expression including expression dominance and biased homoeolog expression (Hegarty et al. 2008; Rapp et al. 2009; Flagel and Wendel 2010; Grover et al. 2012; Buggs 2013; Yoo et al. 2013), and changes in epigenetic modifications (Wang et al. 2004; Madlung and Wendel 2013).

In addition to these dynamic responses to polyploidization, there are potential stoichiometric disruptions caused by the combination of two nuclear genomes but inheritance of only one set of progenitor organellar genomes (usually maternal), suggesting a cytomolecular dimension to allopolyploid evolution. Many aspects of cytomolecular coevolution have been considered for diploid plants and animals (Rand et al. 2004; Wolf 2009; Caruso et al. 2012; Burton et al. 2013), addressing a number of key topics such as the effects of cytomolecular interaction on population fitness (Caruso et al. 2012; Burton et al. 2013), the occurrence of compensatory coadaptive cytomolecular mutations (Rand et al. 2004), participation of cytomolecular coordination in hybrid breakdown (Burton et al. 2013), and cytomolecular-epistasis-controlled nuclear genome imprinting (Wolf 2009). To date, though, the special circumstances surrounding cytomolecular evolution in polyploids remains largely unexplored. Previously, we investigated how homoeologous nuclear genes of Gossypium allopolyploids...
encoding subunits of one protein complex evolved in a new context where they need to interact with a subunit encoded by a gene from the plastome, inherited (in cotton) from only one of the two progenitor diploids (Gong et al. 2012). The model protein complex we utilized is Rubisco (Ribulose 1,5-bisphosphate carboxylase/oxygenase), an essential enzyme in carbon fixation during photosynthesis, which functions as octamer holoenzymes of small subunits (SSUs) encoded by a nuclear rbcS multigene family and large subunits (LSUs) encoded by a single plastid rbcL gene (Rodermel et al. 1996). After characterizing rbcS and rbcL genic compositions in Gossypium, we explored their cytonuclear coordination at the genomic level, showing postpolyploidy, intergenomic, maternal-to-paternal gene conversion between nuclear homoeologs (Gong et al. 2012), in the direction opposite to that exhibited overall in Gossypium polyploids (Salmon et al. 2010; Flagel et al. 2012; Paterson et al. 2012; Guo et al. 2014). At the transcriptional level, biased maternal rbcS homoeolog expression was also demonstrated.

Intrigued by these findings for Gossypium, we asked whether similar cytonuclear coordination would be observed as a general phenomenon for rubisco evolution in other polyploids. Toward that end, we selected four exemplary angiosperm polyploid lineages, Arabidopsis, Arachis, Brassica, and Nicotiana, each of which has a well-understood phylogeny with extant model diploids and stabilized descendant allopolyploids. The rubisco rbcS and rbcL genes in each lineage were characterized. Within each lineage, phylogenies were constructed for rbcS gene paralogs and orthologs in the diploid species and placed in the context of their species divergence. By analyzing the rbcS gene sequences in representative parental diploids and allopolyploids, we demonstrate a consistent pattern of postpolyploidy gene conversion among rbcS homoeologs. In addition, biased homoeolog expression of paternal homoeologs carrying maternal conversions was also confirmed in most polyploid species. These results have general significance with respect to cytonuclear evolution in plant allopolyploids.

**Results**

**Maternal Inheritance and Divergence among rbcL Genes**

rbcL genes from diploid and polyploid species of all four polyploid lineages were cloned and sequenced (table 1). Except in Brassica, there are from 0.43% to 0.65% nonsynonymous substitutions between the LSU proteins of the parental diploid species in each lineage. As expected, each polyploid has the copy inherited from the maternal parents. In Brassica, no amino acid differences exist between the parental diploid species (table 1). Similar to observations for rbcL genes in diploid cottons (Gong et al. 2012), diverged amino acid residues cluster in the C-terminal α/β barrel domain and/or N-terminal domains of LSU subunits (table 1), which together form the active sites for rubisco (Spreitzer and Salvucci 2002). Notably, amino acid substitutions are also observed in the middle regions following the C-terminal domains, where the LSUs interact with the SSUs (Spreitzer and Salvucci 2002; Spreitzer et al. 2005). These raise the possibility of coevolutionary pressures in allopolyploids that might inherit divergent parental SSUs.

**rbcS Composition in Diploids**

Prior to cloning rbcS homoeologs in the polyploids, we cloned parental rbcS genes and aligned these into orthologs for inferences of homoeology in the polyploids. As shown in the exemplary rbcS sequence alignment for Arabidopsis (fig. 1), gene structure (introns/exons) was ascertained using cloned cDNAs. rbcS genes in most genera have three exons separated by two introns, the latter accumulating most of the substitutions and indels (fig. 1 and supplementary figs. S1–S3, Supplementary Material online). In Nicotiana, however,

*Accession listed beside each species names. Allopolyploids are shown in the central column, with maternal and paternal parents on the left and right, respectively.
Fig. 1. Alignment of Arabidopsis rbcS orthologs and homoeologs with featured SNPs and gene conversion events highlighted in the exons. An exemplary cloned cDNA at the bottom (in light blue) is aligned with genomic rbcS homologs to ascertain rbcS exons/introns structure. Only featured SNPs and gene conversions in exonic regions are illustrated here. Conserved nucleotides in all orthologs and homoeologs are shown in gray. Homologs of maternal and paternal origins are highlighted in orange and green, respectively. Species-specific SNP positions (748 and 776) are marked by yellow ovals above the alignment blocks. Multiple genome-unique SNPs in diploid parental copies are shown in orange (maternal) and green (paternal) text.
there are three introns separating the coding region into four exons (supplementary fig. S3, Supplementary Material online). In exons of rbcS paralogs in each parental diploid, there are species-specific (consistent polymorphic substitution shared by all paralogs in the same species) and genome-unique (existing in a unique genome) single-nucleotide polymorphisms (SNPs), denoted in the exons of the alignment (fig. 1, supplementary figs. S1–S3, Supplementary Material online). Two groups of genome-unique SNPs are further recognized: Category I includes genome-unique SNPs present in at least two paralogs of a specific species; category II SNPs are carried by only one rbcS paralog (fig. 1, supplementary figs. S1–S3, Supplementary Material online; table 2). Species-specific SNPs shared by all paralogs of the same species were detected only in Arabidopsis, where the two species-specific SNPs have "C (Cytosine)" and "A (Adenine)" at the 748th position and "T (Thymine)" and "C (Cytosine)" at the 776th position in Arabidopsis thaliana and A. arenosa, respectively (fig. 1, table 2).

To compare the fixation rates of exonic, genome-unique SNPs, we tabulated their numbers in diploids of each lineage and included data generated previously for Gossypium species (supplementary fig. S4, Supplementary Material online, table 2). Because genome-unique SNPs in category I exist in multiple paralogs of the same diploid species, these SNPs are treated as nucleotide mutations that are fixed and spread by local gene conversions. As shown, the proportions of fixed genome-unique SNPs in category I are variable among lineages, ranging from 1.04% in Arachis to 4.47% in Brassica (table 2). This divergence is related to organismal divergence time (supplementary fig. S4, Supplementary Material online, table 2), with the notable exception of Brassica. For this genus, in which the progenitor diploids are thought to have diverged approximately 3.5 Ma (Higgins et al. 2012), a much higher proportion of genome-unique SNPs (4.47%) in category I is observed. This is significantly higher than in similarly aged Arachis (diverged 3.5 Ma, Seijo et al. 2007), older Arabidopsis (diverged 5 Ma, Jakobsson et al. 2006) and Gossypium (Wendel et al. 2010), or even the more ancient Nicotiana lineage (diverged 15 Ma, Leitch et al. 2008) (supplementary fig. S4, Supplementary Material online, and table 2). Possible explanations for this exceptional divergence in Brassica are discussed below. Accordingly, Brassica was not included in the correlation calculation but still is shown in the regression plot (supplementary fig. S4, Supplementary Material online). Apart from Brassica, a significant correlation was observed in fixation rate of exonic category I genome-unique SNPs ($R^2 = 0.53585, P < 0.05$) (supplementary fig. S4, Supplementary Material online).

To understand the evolutionary history of the diploid rbcS orthologs, phylogenetic trees were constructed in the context of diploid species divergence within each lineage (fig. 2). In all cases, gene copy numbers are based on published genome sequences in conjunction with the cloning and sequence data. Unusually divergent rbcS paralogs are shown in blue, which includes orthologous groups 1A and a3 in Arabidopsis, A1 and B1 in Arachis, A1 and C1–C3 in Brassica, and S5 and T5 in Nicotiana. Because gene conversion at the diploid level has homogenized sequence pairs in many cases, the number of different gene copies is lower than the number of actual gene copies. In figure 2, homogenized copies are shown by interacting double helices. Among the species studied, the number of rbcS orthologs ranges from 4 to 12 (fig. 2). In some cases, autapomorphic substitutions arose following polyploidy, confirming the presence of gene converted and hence homogenized duplicates at the diploid level. There was no loss of any homoeolog in any of the four allopolyploids studied.

Gene Conversion Events Following Allopolyploidy

Comparison of each rbcS homoeolog with their parental orthologous copies revealed a number of autapomorphic nucleotide substitutions that have accumulated after formation of each polyploid (table 2). At the low end, in Nicotiana tabacum, 11 autapomorphic SNPs were detected, representing 2.40% of the exonic nucleotide positions. The higher levels were for A. suecica and Gossypium hirsutum with the proportions 7.55% and 8.01% (table 2). As shown in supplementary figure S5, Supplementary Material online, the level of autapomorphic SNP presence is dependent on polyploid age; more recent polyploids have fewer SNPs. For example, in Arachis hypogaea and Brassica napus, polyploids of similar age (> 5,000 and < 10,000 years ago), almost equivalent proportions of autapomorphic SNPs are detected (3.73% and 3.35%, respectively). Nicotiana tabacum, a polyploid estimated as less than 200,000 years old, has an exceptionally small proportion of SNPs, whereas for A. suecica and G. hirsutum, the ancient polyploid species in our analysis (formed 12,000–300,000 years ago and 1–2 Ma, respectively) has the higher proportion of exonic autapomorphic SNPs (supplementary fig. S5, Supplementary Material online).

We inferred the parental origin of each homoeolog in the polyploids through comparisons with their diploid orthologs. We then inspected each homoeolog for genome-diagnostic SNPs from a different rbcS gene, mindful of the possibility (Gong et al. 2012) of intergenomic gene conversions. Alternatively, intragenomic gene conversions are implicated when they exclusively involve diagnostic SNPs among
homoeologous copies of the same parental origin. A summary of these inferences of the intra- and intergenomic gene conversions is illustrated for each lineage (figs. 1 and 3, supplementary figs. S1–S3 and S6–S8, Supplementary Material online). Together with previous findings for *Gossypium* polyploids, we note several features of the inter/intragenomic gene conversions: 1) most conversion events were intergenomic (figs. 1 and 4 and supplementary figs. S1–S3, Supplementary Material online). Specifically, except for three intragenomic conversions in *A. suecica* (1st, 2nd, and 4th events among nine gene conversion events; fig. 1), there were no intragenomic conversions detected in other studied polyploids, including *Gossypium* (Gong et al. 2012); 2) similar to the short *rbcS* genes in *Gossypium* (Gong et al. 2012), intergenomic events altered the originally identical *rbcS* duplicates (those linked by anastomosing lines in fig. 2) so they became distinguishable (different) at the polyploid level—for example, two identical paralogs in *A. arenosa* became two different homoeologs, *A. suecica*—Asa2a and *A. suecica*—Asa2b, when the latter copy obtained maternal diagnostic SNPs via 5th–9th intergenomic conversion events (fig. 1); and 3) most of the intergenomic events occurred in the paternal homoeologs, using templates from the maternal homoeologs (figs. 1, 4, and supplementary fig. S1–S3,

![Fig. 2.](image) Evolutionary history of *rbcS* genes in diploid species in four genera. Gene names in maternal and paternal diploid species are denoted in orange and green, respectively. Unusually divergent *rbcS* paralogs are shown in blue, which includes orthologous groups 1A and a3 in *Arabidopsis*, A1 and B1 in *Arachis*, A1 and C1–C3 in *Brassica*, and S5 and T5 in *Nicotiana*. Because gene conversion at the diploid level has homogenized sequence pairs in many cases, the number of different gene copies is lower than the number of actual gene copies; homogenized copies are shown by anastomosing double helices.
Supplementary Material online)—in other words, gene conversions occurred preferentially in the direction of introducing maternal-diagnostic SNPs into paternal homoeologs (simplified as “maternal-to-paternal” conversions). This is also the case in *Gossypium* polyploid species (Gong et al. 2012). Here, this is exemplified in *A. suecica*, where five of six intergenomic conversions entailed maternal-diagnostic SNPs detected in paternal homoeologs (fig. 1).

Protein sequences of all *rbcS* orthologs and homoeologs were predicted. Within the protein alignment, the aforementioned gene conversions were discovered to generate nonsynonymous amino acid substitutions only in *A. suecica* and *Arac. hypogaea*; most gene conversions did not result in amino acid changes (figs. 3, 4, and supplementary figs. S6–S8, Supplementary Material online). In *A. suecica*, the 7th and 8th conversion events brought maternal-specific “G (Glycine)” and “T (Threonine)” residues into the paternal homoeolog “*A. suecica*-Aa2b,” in the process replacing the paternal amino acids “N (Asparagine)” at those two positions (fig. 3). Similarly, in *Arac. hypogaea*, the first conversion event caused nonsynonymous amino acid substitution in “*Arac. hypogaea*-AhB3b” homoeolog (supplementary fig. S6, Supplementary Material online).

**Fig. 3.** Alignment of SSU proteins encoded by *rbcS* orthologs and homoeologs in *Arabidopsis* lineage. Maternal and paternal origin of each *rbcS* homolog is highlighted in orange and green color, respectively. Conserved amino acids are shown in gray, whereas polymorphic amino acid substitutions are in black. The synonymous/nonsynonymous substitutions caused by gene conversions are marked using different diamonds as in figure 1. Essential interface regions in SSUs, the predicted βA/βB loops where SSUs contacts with LSUs, are shown by open gray boxes.

**Fig. 4.** Summary of gene conversions in multiple SSU domains. Gene conversion events among homoeologs from the same and different genomic origins, defined as intra- and intergenomic conversion events, are shown in the right and left panels, respectively. Within each functional SSU domain (on the x axis), the total numbers of conversion events introducing synonymous and nonsynonymous amino acid substitutions are denoted by green and blue bars, respectively. The pink and red frames around each green and blue bar highlight conversion directions, paternal to maternal (paternal state introduced into maternal homoeologs) and maternal-to-paternal (maternal state introduced into paternal homoeologs), respectively.

Cytonuclear Evolution of Rubisco.

doi:10.1093/molbev/msu207

MBE

at Iowa State University on November 17, 2015 http://mbe.oxfordjournals.org/
We summarized the distribution of types of gene conversion across the different SSU functional domains (fig. 4). SSU proteins were partitioned into four domains: Transit peptide (signaling peptide for pre-SSU targeting plastid and transportation to plastid); transit-loop interval region (mainly composed by α-helix A between signal peptide and βA/βB loop); βA/βB loop region (interface of SSU with LSU, which includes the β-strands and their enclosed loop); and all other β strands at the C-terminal end (Spreitzer and Salvucci 2002; Genkov and Spreitzer 2009; Kim et al. 2010). No gene conversion was detected in the transit-loop interval in any polyploid. Consequently, this region was excluded from the summary bar chart (fig. 4). In addition, the major intergenic conversions preferentially occurred in the transit peptides and the C-terminal β strands rather than in the βA/βB loop region where SSUs interact with LSUs in the rubisco holoenzyme. Finally, in terms of the intergenic conversion directions, the preferred “maternal-to-paternal” conversion events were detected in each SSU domain. All three nonsynonymous, intergenic conversions introduced maternal amino acids into the paternal homoeologous SSUs (fig. 4).

### Biased Expression of Paternal rbcS Homoeologs with Maternal-Converted Regions

To address whether there is biased homoeolog expression-related genomic origin of rbcS genes and if this is correlated with intergenic gene conversions, we compared transcript levels for all polyploids (table 3). Homoeolog expressions were determined by multiplying the read coverage proportion of their specific SNPs by the total mapped rbcS reads (table 3 and supplementary table S4, Supplementary Material online). Within all polyploid species except B. napus, the paternal homoeologs with converted maternal segments were always significantly more highly expressed than their homoeologous counterparts without such intergenic conversions (table 3). In contrast, in B. napus, the paternal homoeolog without gene conversion (BnC6a) had significantly higher expression than its counterpart paternal homoeolog (BnC6b) with maternal-to-paternal conversions (table 3).

### Discussion

Here, we extend our results on cytonuclear coevolution of rubisco genes in Gossypium allotriploids (Gong et al. 2012) to four other model allotriploids, Arabidopsis, Arabis, Brassica, and Nicotiana. Our goal was to explore the extent to which the genic and transcriptional biases observed in cotton are mirrored in other allotriploids and thereby gain insight into the generality of our indications of cytonuclear coevolution. Specifically, our aims were to discern the genic copy numbers and structures of nuclear rbcS genes in different genera, their propensity for “gene conversion” at both the diploid and allotriploid levels, and the possible interplay between these dynamics and those of the plastid-encoded rbcL gene. We further wished to assess whether there is biased expression of homoeologs in other genera, how this relates to gene conversion, and the degree of similarities among multiple, phylogenetically dispersed angiosperm allotriploids.

### Potential Selection Pressure for Cytonuclear Coordination among rbcS Genes in Polyploids

rbcL is widely utilized as a slowly evolving plastid gene for purposes of phylogenetic reconstruction of angiosperm families and orders. Accordingly, we expected little sequence evolution among con-generic species and such is indeed the case for the data presented here (table 1). Yet several nonsynonymous differences are observed between rbcL genes from different diploid parents (except in Brassica), documenting maternal inheritance of the plastome in the allotriploids, and indicating possible functional regions of LSUs that could conceivably apply selective pressure for optimization of biparentally inherited rbcS-derived SSU proteins. Specifically, during diploid divergence, the LSU in three of the four genera studied here accumulated several amino acid substitutions at both the C- and N termini. Considering the C- and N-terminal domains are the catalytic centers and where the subunit interfaces with SSUs (Spreitzer et al. 2005; Genkov and Spreitzer 2009), the possibility exists that selection has operated on rbcS genes in the allotriploid to optimize rubisco holoenzyme activity. As discussed below, the rbcS data are suggestive of this mechanism of compensation, for

*The homoeolog without maternal-to-paternal conversions is listed first.

*Negative expression differences are interpreted as biased expression of homoeolog copies with maternal-to-paternal gene conversions relative to the homoeolog without such conversions.

*Those two RNA sequencing experiment involved three biological replicates generated from mature leaves (Peggy Ozias-Akins, unpublished data and SRA056385 in Yoo et al. 2013). Expression difference shown is from one replicate of each experiment. Significant expression differences are consistently identified at the same P value level for all other replicates (not shown).
most genera studied. Notably, *Brassica* is exceptional, with no amino acid divergence between parental LSUs, yet it too exhibits signatures of cytonuclear coevolution (see below), thereby implicating selection operating on other aspects of cytonuclear regulation.

Concerted Evolution of *rbcS* Genes in Diploid Species

In angiosperms studied to date, similarities of *rbcS* genes within species are often observed (Gong et al. 2012), especially among tandem *rbcS* paralogs, with lower similarities among physically dispersed *rbcS* paralogs. These observations, combined with phylogenetic evidence showing even lower similarities of *rbcS* orthologs in different species, have been taken as evidence that *rbcS* genes frequently are subjected to "concerted evolution" or sequence homogenization via gene conversion (Meagher et al. 1989; Clegg et al. 1997).

Concerted evolution is also evident in most species studied here (fig. 2). These inferences are based on two sources of information, that is, cloning and sequencing data, which provide diagnostic SNPs for *rbcS* paralogs, and genome sequence data, which provides gene number counts. The former includes both species-specific and genome-unique SNPs of the same genus. Species-specific SNPs reflect homogenization among paralogs within species, presumably from a gene conversion process that is evolutionally sporadic. Interestingly, this process appears to be insufficiently frequent to completely homogenize paralogs but sufficiently common that its footprints are visible in the current suite of *rbcS* genes in each species. Similar results were previously reported for *Gossypium* (Gong et al. 2012). Genome-unique SNPs in each species, as described previously, can be further sorted into two categories, which have experienced distinct evolutionary histories. Category I includes genome-unique SNPs present in at least two paralogs of a specific species (table 2), which likely are derived from relatively recent homogenization via local/minor conversions among several rather than all paralogs. Category II includes most genome-unique SNPs (table 2), existing in single *rbcS* paralogs. We infer that these SNPs are the most recent substitutions generated in specific *rbcS* paralogs, such that they have not been homogenized across any other paralog. Possible mechanistic hypotheses for this failure to homogenize include recency of these SNPs relative to the pace of gene conversion, and/or spatial dispersal of these paralogs from other paralogs, so that the opportunities for gene conversion are lower.

Another interesting dimension of our data is the relatively consistent fixation rate of genome-unique SNPs in different lineages. Given a significant positive linear correlation of the proportion of category I genome-unique SNPs with divergence time in most genera (supplementary fig. S4, Supplementary Material online), the balance between nucleotide mutations in *rbcS* genes and their erasure via homogenization may generally be similar among plant lineages. This suggestion clearly will benefit from additional study using other plant genera. It may be, for example, that life history features such as mating system, population level dynamics, and effective population size create variation in this mutation fixation balance. The higher fixation rates observed in the obligately outcrossing *Brassica*, for example, might reflect these factors (Wright et al. 2008; Ivanov and Gaude 2009).

One somewhat ironic observation is that in some cases, more *rbcS* genes are detectable at the allopolyploid than the diploid level. This reflects both the absence of gene loss following allopolyploidy and the evolution of novel SNPs postpolyploidy, which render previously identical paralogs (at the diploid level) nonidentical. For instance, in *Arabidopsis*, the similar but different *A. suecica*-Asa2a and *A. suecica*-Asa2b (corresponding to two identical *A. arenosa*-a paralogous copies) and in *Gossypium* (Gong et al. 2012), one more short-type *rbcS* homoeolog, are examples where different genes are observed at the polyploid level, caused by mutation being ahead of homogenization. A second example involves multiple distinct paralogs in one diploid species and a single group of identical paralogs in another diploid species, such as in *Brassica*, where there is orthology between *B. oleracea*-C8a and *B. oleracea*-C8b and two identical *B. rapa*-A6 genes, and between *B. rapa*-A2a and *B. rapa*-A2b and two identical *B. oleracea*-C6 genes (fig. 2).

The more extreme cases of escape from homogenization involve the near-independent *rbcS* copies in each diploid species of each lineage studied (blue lines in fig. 2). As proposed for *Gossypium*, this relative independence may be related to their distinct chromosomal locations (Gong et al. 2012). For example, in *A. thaliana*, three paralogs (1B, 2B, and 3B), with relative higher sequence similarities, are all located on chromosome 5, whereas the 1A paralog with the least similarity is on chromosome 1. In *Gossypium*, relatively independent long and short paralog groups are also clustered on chromosomes 11 and 1, respectively. In *Brassica*, three identical *B. rapa*-A1 copies and its three *B. oleracea*-C orthologs (-C1 to -C3) have the lowest sequence similarity to the other paralogs in each diploid species (fig. 2). A parsimonious explanation for this observation is that after the originally clustered gene copies translocated to new genomic regions in the common ancestor of *B. rapa* and *B. oleracea*, the three *rbcS* paralogs in *B. rapa* began to evolve independently from other *rbcS* paralogs, while still being subject to local gene conversion homogenization pressures; the other three gene copies in *B. oleracea*, however, came to be distinguishable via novel mutations. In brief, physical dispersal could protect independent copies from global homogenization.

Concerted Evolution of *rbcS* Homoeologs in Allopolyploids

Because allopolyploidy entails the merger of two sets of *rbcS* genes, gene conversion can, in principle, homogenize not only paralogs but also homoeologs. Notably, there are many autapomorphic SNPs in the allopolyploids, some identified in genomic conversion regions (shown as pink SNPs in each alignment file). Thus, these autapomorphic SNPs are new SNPs introduced by homogenization via gene conversion across homoeologs. These mutations appear to be related to the time since polyploidization, as the relatively older *A. suecica* and *G. hirsutum* have more of these SNPs than are
observed in the relatively younger *Arac. hypogaea* and *B. napus* sequences (supplementary fig. S5, Supplementary Material online).

**Genomic Cytonuclear Coordination of *rbcS* in Allopolyploids**

Intergenomic coadaptation or coordination between the nuclear and cytoplasmic organellar genomes is an essential component of evolutionarily successful hybridization events (Burton et al. 2013). Intergenomic interactions may be interrupted when hybridization occurs between genetically divergent populations, which combine divergent nuclear genomes with only a single set of cytoplasmic genomes. With respect to the rubisco complex, diverged nuclear *rbcS* homoeologs inherited from both parental species may be posited to be targets of selection following genome merger and doubling at the time of polyploid formation, in response to their new cellular milieu containing only the maternal cytoplasm.

As shown in *Gossypium*, one path toward reducing potential cytonuclear conflict is "maternal-to-paternal," intergenomic homogenization of *rbcS* homoeologs, presumably to stabilize or optimize rubisco holoenzyme activity. Specifically, in the N-terminal transit peptide region, which possesses the necessary information for SSU targeting and transport into the chloroplast (Bruce 2000; Lee et al. 2002), the potential relief from inefficient recognition and transport of paternal SSUs into the maternal chloroplast could conceivably be achieved by intergenomic, nonsynonymous gene conversions of paternally inherited *rbcS* copies. This possibility is exemplified by the 1st conversion event in *Arac. hypogaea-AhB3b* (supplementary figs. S1 and S7, Supplementary Material online). Similarly, at the C-terminal β-strands domain, which maintains holoenzyme structural stability and also potentially regulates LSU/SSU interactions (Esquivel et al. 2002; Spreitzer and Salvucci 2002), paternal SSU homoeologs obtained maternal-like, C-terminal β-strands via intergenomic, nonsynonymous conversions both in *Gossypium* and the currently studied genera (fig. 4). This group of converted, paternal SSUs could also be favored during or after the assembly process with the maternal LSUs in the holoenzyme. However, in the βA/βB loop region where SSU proteins contact LSUs (Spreitzer et al. 2005; Genkov and Spreitzer 2009), there were no amino changes in the currently studied allopolyploids that were introduced by intergenomic conversions, so all paternal SSUs maintained their original protein sequences. Two scenarios can explain this observation: 1) paternal SSUs have sufficient compatibility with the cytoplasmic LSU at this interface region, such that fitness is not compromised and 2) insufficient time has elapsed for "more fit" genomic conversions to arise. In *G. hirsutum*, the loop regions of all divergent paternal SSUs have been replaced by the maternal loops via nonsynonymous, maternal-to-paternal gene conversions (Gong et al. 2012), suggesting an evolutionary future for these "caught in the act" younger allopolyploids. Targeting mutation experiments with artificial maternal-to-paternal conversions in the βA/βB loop regions of paternal *rbcS* homoeologs would be interesting experiments to evaluate these scenarios.

The evidence presented here is consistent with, but does not prove, preferential selection for the products of intergenic, maternal-to-paternal gene conversions (among intra, maternal-to-paternal or paternal-to-maternal events) across paternal nuclear homoeologs, followed by homogenization of the selected conversions across other copies originating from the paternal genome. Specially, for the polyploid species, in addition to the maternal-to-paternal intergenic conversions, both intragenomic conversions and paternal-to-maternal, intergenic conversions have probably occurred in paternal *rbcS* homoeologs following polyploidization, detected across different SSU domains (fig. 4). Cytonuclear co-evolutionary pressure may thus have preferentially selected intergenic, maternal-to-paternal conversions. Given the relatively recent formation (<0.5 Ma) of all allopolyploids analyzed here, intragenomic and paternal-to-maternal conversions remain evident, perhaps having had insufficient time to homogenize the putatively beneficial maternal-to-paternal conversions across all *rbcS* copies, some of which retain their original parental diagnostic SNPs. In *Gossypium*, where polyploidy originated 1–2 Ma, the maternal, genome-specific SNPs have been homogenized across all paternal homoeologs. Additional evidence from other genera will further inform this possible evolutionary scenario.

A special case exists in *B. napus*, which inherited the maternal diploid LSUs with no amino acid divergence from the paternal LSUs. Given this observation, and the assumption that this would eliminate the possibility of selection at the level of SSU/LSU interaction, one might expect random interchanges among homoeologs irrespective of parental origin. Yet even in *Brassica* only intergenic, maternal-to-paternal conversions were detected (in the paternal homoeolog, BnC6b). Relevant to this observation is the fact that SSU proteins need to be recognized by multiple cytoplasmic factors and transported to the surface membrane of the maternally derived plastid, where they are subjected to transmembrane transport into the plastids. It is possible that the gene conversion observed here reflects selection at this level, during some stage or process involved with maternally derived trans-membrane transport (Bruce 2000; Lee et al. 2002). Testing this idea is experimentally feasible, for example, through targeting mutations in the maternal-to-paternal conversion region in the BnC6b homoeolog and comparing its accumulated SSU proteins in the plastid stroma with SSU proteins from control *B. napus* individuals. At present, we are reporting an intriguing phenomenon that is suggestive of a newly described dimension of cytonuclear evolution.

**Transcriptional Cytonuclear Coordination of *rbcS* Homoeologs**

In addition to the gene sequence data and gene conversion evidence for cytonuclear accommodation to the polyploid state, we also explored gene expression levels to test whether there is biased expression of maternally derived *rbcS* genes. In three of the four allopolyploids (all but *B. napus*), relative to
the paternal homoeologs with no intergenomic conversion, paternal homoeologs with maternal-to-paternal conversions uniformly displayed preferential expression, consistent with our previous observations in Gossypium (Gong et al. 2012). This repeatedly observed, biased homoeolog expression among diverse allopolyploids is suggestive of selection at the level of transcript accumulation with a fitness advantage for SSU-encoding transcripts that carry maternal-like sequences. We note that biased expression of the paternal homoeolog with no maternal conversions was observed in Brassica. It could be explained by two possible scenarios: 1) relative weak selection of maternal LSU in plastid, which is identical with paternal LSU; and 2) insufficient time for transcriptional selection to arise.

Here, we have explored two dimensions of possible coordination and regulation of rubisco component subunits following allopolyploidization in plant species. We have confirmed that concerted evolution among divergent ancestral, duplicated copies of rbcS genes is a consistent feature of allopolyploid plants. We have shown that interparalog gene conversion is common at the diploid level and that it continues among homoeologs at the allopolyploid level, with a preferential occurrence of maternal-to-paternal, intergenomic conversions in signaling and regulatory domain of SSU genes. In most allopolyploids, this is accompanied by biased expression of paternal homoeologs carrying maternal-like gene conversions. Taken together, these data are consistent with cytonuclear selection following the reunion of two diverged genomes in a single cytoplasm as a consequence of allopolyploid speciation. Importantly, our analysis focuses only on cytonuclear coevolution of rubisco genes at the DNA and RNA levels; clearly much work remains for other potentially relevant dimensions of the problem, including studies of incorporation efficiency of divergent homoeologous SSUs into the rubisco holoenzyme, similar explorations of other cytonuclear coencoded complexes in cytoplasmic organelles, stoichiometric changes in organelle and organellar genome abundances in each polyploid cell compared with the cells of their diploid parents, and many other dimensions of protein trafficking into organelles.

Materials and Methods

DNA and RNA Extraction and cDNA Synthesis

Four angiosperm polyploid lineages were selected, each of which included model progenitor diploids and derived allopolyploids (table 1). Fully expanded leaves of each species in each genus were sampled at the same developmental stages. After washing with Diethylpyrocarbonate (DEPC)-treated water, leaves were divided into two parts, which were used for DNA and RNA extraction, respectively. DNA extraction, RNA extraction, and cDNA synthesis were carried out following methods described previously (Gong et al. 2012).

Primer Design, Cloning, and Sequencing

rbcL is highly conserved among closely related species (Gielly and Taberlet 1994). We downloaded from National Center for Biotechnology Information (NCBI) all available rbcL genes in the genera studied for primer design (supplementary table S1, Supplementary Material online). For lineages not represented in the NCBI collection, the rbcL gene sequence from a closely related genus was used as the query sequence to BLASTn against the expressed sequence tags (ESTs) in PlantGDB (http://www.plantgdb.org/, last accessed April 28, 2014; supplementary table S1, Supplementary Material online). Manually aligned sequences of ESTs on the 5’- and 3’-end of the original BLAST query sequence (covering the start and stop codon, respectively) were used for primer design. Degenerate primers used to amplify full-length rbcL genes in each species are tabulated in supplementary table S2, Supplementary Material online.

Available genome assemblies of sequenced species and their ESTs deposited in PlantGDB were collected for rbcS primer design (supplementary table S2, Supplementary Material online). The rbcS genomic sequences of that species, or a related species in the same genus, or in some cases a related genus, were used as query sequences with BLASTn against genome assemblies or EST sequences. Significant homologous copies in each genome assembly or the manually aligned sequences of ESTs on the 5’- and 3’-end of the original BLAST query sequence were used for primer design. Primers specifically amplifying orthologs or homoeologs of rbcS in each species are tabulated in supplementary table S2, Supplementary Material online.

Polymerase chain reaction (PCRs) and PCR programs amplifying rbcL and rbcS genes, PCR product cloning, and sequencing followed the methods described earlier (Gong et al. 2012). Only the annealing temperature (at the initial step and in stabilized loops) was adjusted for each primer (supplementary table S2, Supplementary Material online). The same sets of primers designed above for amplifying genomic rbcS genes were also used for amplification of rbcS cDNAs. Final sequenced rbcL and rbcS genes were deposited into GenBank with accession numbers as KM025240–KM025251 and KM025252–KM025337, respectively.

When amplifying the rbcS genomic or transcript copies in each species, to avoid possible false rbcS PCR-recombination artifacts, three parallel independent PCRs were carried out for each primer sample. Only the rbcS copies, having at least 25% supportive clones sequenced in each independent PCR, were accepted as bona fide copies. Cloning and sequencing of the PCR products were also carried out as described (Gong et al. 2012).

Sequence Alignment and Phylogenetic Reconstruction

Sequences were aligned within each genus using the online MAFFT tool v7.122 (Katoh and Standley 2013). After manual adjustment, synonymous and nonsynonymous substitutions in the exons were noted. Phylogenetic histories of the rbcS multigene family in all diploids of each lineage were inferred based on parsimony analysis.
Detection of Homoeologous SNPs and Gene Conversion Events (Nonreciprocal Homoeologous Recombination)

For each genus, genome-diagnostic SNPs (including the species-specific and genome-unique SNPs) and autapomorphic SNPs were inferred in rbcS orthologs and homoeologs, respectively. Genome-diagnostic SNPs were used to determine the parental genomic origin of each homoeolog. Autapomorphic SNPs are defined as novel nucleotides arising at the polyploid level (in either homoeolog). Within the allopolyploid species, the possible exonic rbcS genomic conversion regions or points of “non-reciprocal recombination” (in only one direction from paternal to maternal homoeolog or vice versa; Salmon et al. 2010) were initially inferred using the GENECONV tool (automated recombination detection in triplet sequences), which is incorporated in RDP4 Beta 4.27 software (Sawyer 1989; Martin et al. 2010). Specifically, each rbcS homoeolog in the polyploids was searched against both reference diploid orthologs and other homoeologs: Any recombinations identified between homoeologs of the same genomic origin were inferred as intragenomic conversions, whereas those involving homoeologs of different genomic origin were accepted as products of intergenicomic conversion events. Recombination detection program (RDP)-identified conversion copies were further processed by homemade Perl scripts, which tabulated the SNP information within converted homoeologs as previously described (listing the coordinates in the alignment and nucleotide changes before and after the conversions; Gong et al. 2012). As noted previously, to avoid possible artificial PCR recombinants, only recombinants occurring in at least 25% of the total cloned sequences from each replicated PCR were accepted as true “gene conversion” copies.

Statistical Comparison of rbcS Homoeolog Transcript Level Based on RNAseq

Next-generation RNA sequencing data of all polyploids in four lineages were collected from SRA databases in NCBI and other resources (supplementary table S3, Supplementary Material online). Quality-filtered reads were mapped to all cloned rbcS homoeologs via Bowtie 1.0.0 with stringent perfect match control (Langmead et al. 2009). The final rbcS homoeolog-specific expression proportions were obtained by dividing the mapped reads covering all diagnostic homoeolog-specific SNPs of each homoeolog copy by the total reads mapped to those SNP positions in all expressed rbcS homoeologs. The coverage of each SNP in each homoeolog was searched against both reference diploid rbcS orthologs with and without intergenomic conversions. Recombination homoeolog-specific SNPs of each homoeolog copy by the total reads mapped to those SNP positions in all expressed rbcS homoeologs.

(1) The null hypothesis assumed no homoeolog expression difference in H\textsubscript{converted} versus H\textsubscript{nonconversion}. Hence, the expectation of the expression difference was zero.

\[ E(H_{\text{converted}} - H_{\text{nonconversion}}) = 0 \]

(2) The variance of the homoeolog expression difference in H\textsubscript{converted} versus H\textsubscript{nonconversion} was derived:

\[ \text{Var}(H_{\text{converted}} - H_{\text{nonconversion}}) = \text{Var}(H_{\text{converted}}) + \text{Var}(H_{\text{nonconversion}}) - 2 \times \text{Cov}(H_{\text{converted}}, H_{\text{nonconversion}}) \]

Under the assumption of the summed proportions of all rbcS homoeologs being 1, the probability of obtaining the observed combination of rbcS homoeolog expression should follow the multinomial distribution. According to the known variance of one variable and covariance of two component variables in the multinomial distribution,

\[ \text{Var}(H_{\text{converted}}) = N_{\text{total}} \times p_{\text{Hconverted}} \times (1 - p_{\text{Hconverted}}) \]

\[ \text{Var}(H_{\text{nonconversion}}) = N_{\text{total}} \times p_{\text{Hnonconversion}} \times (1 - p_{\text{Hnonconversion}}) \]

\[ \text{Cov}(H_{\text{converted}}, H_{\text{nonconversion}}) = -N_{\text{total}} \times p_{\text{Hconverted}} \times p_{\text{Hnonconversion}} \]

in which \( N_{\text{total}} \) was the total expression of all rbcS homoeologs in polyploid species, and \( p_{\text{Hconverted}} \) and \( p_{\text{Hnonconversion}} \) were expression proportions of homoeologs with and without intergenicomic conversions.

(3) A final \( Z \) statistic was calculated with all terms replaced by their values calculated as above:

\[ Z \text{ statistic} = \frac{\left\{ \text{Observed}(H_{\text{converted}} - H_{\text{nonconversion}}) \right\}}{\left[ \text{Var}(H_{\text{nonconversion}} - H_{\text{nonconversion}}) \right]^{1/2}} \]

\( P \) value of each estimated \( Z \) statistic was estimated based on the standard normal distribution.
