CHAPTER 1 Introduction

A large variety of systems (e.g. communication protocols over lossy channels, client-server protocols with unreliable servers, and distributed leader-election algorithms) exhibit probabilistic behavior in which the systems evolve from one configuration to another following a certain pre-specified probability distribution. Such probabilistic behaviors are often modeled using discrete time Markov chains (DTMC), continuous time Markov chains (CTMC), and Markov decision processes (MDP). Several techniques and tools have been developed to prove the correctness (in a probabilistic sense) of these system models. One such technique that automatically verifies the conformance of probabilistic systems modeled as DTMC, CTMC, or MDP (Roy and Gopinath (2005); Norman and Shmatikov (2006); Duflot et al. (2006); Kwiatkowska et al. (2008)) against desired properties expressed in probabilistic temporal logic (e.g., PCTL from Hansson and Jonsson (1994) or CSL from Aziz et al. (2000)), is called probabilistic model checking.

Broadly, there are two categories of probabilistic model checking methods. The first category, typically referred to as the numerical method (see Hansson and Jonsson (1994); Bianco and de Alfaro (1995); Courcoubetis and Yannakakis (1995); Aziz et al. (2000); Baier et al. (2003)) relies on exploration of the entire state-space of the probabilistic system and applies linear equation solvers to obtain the probability with which the system satisfies a property. In contrast, the other method, referred to as the approximate or statistical method (see Younes and Simmons (2002); Herault et al. (2004); Sen et al. (2005)), samples a finite set of paths in the system and infers the approximate probability of satisfaction of a property by the whole system using statistical arguments and probabilistic analysis. While the numerical method provides exact solutions, it requires complete knowledge of the system and may fail for systems
with a large state space (known as the state-space explosion problem). It is in this situation that sampling-based statistical methods are useful. However, two important issues need to be addressed before any statistical verification approach can be applied effectively: the number of sample paths to simulate and the length for each sample path.

The sampling method explores only a portion of the state space of the system and therefore the accuracy of the verification results depends on the size of the sample (i.e., the number of sample paths, \( N \)). This value of \( N \) is typically obtained from well-known probabilistic bounds that ascertain the closeness of the estimate to the actual probability with respect to certain pre-specified error limit (\( \epsilon \)) and confidence parameter (\( \delta \)).

By definition, the sampling method can consider only paths of finite length. This is not a problem when the property under consideration has a specific bound (as for a bounded path property): \( \varphi_1 \mathcal{U}^k \varphi_2 \), i.e., \( \varphi_2 \) must be satisfied within \( k \) steps from the start state and in all states before that \( \varphi_1 \) must be satisfied. This implies that finite paths of length \( k \) are sufficient to verify such properties.

However, the property of interest may be unbounded\(^1\), i.e., \( \varphi_1 \mathcal{U} \varphi_2 \). The semantics of the property states that a path satisfies it if and only if there exists a state in the path which satisfies \( \varphi_2 \) and in all states before that state \( \varphi_1 \) is satisfied. Note that \( \varphi_1 \) can be satisfied any number of times in a path before \( \varphi_2 \) is satisfied for the first time. Therefore, in any path of finite length where every state satisfies \( \varphi_1 \land \neg \varphi_2 \), it is impossible to infer whether any extension of the path will eventually satisfy or not satisfy \( \varphi_1 \mathcal{U} \varphi_2 \). The existing statistical methods for probabilistic model checking either assume that an appropriate bound is given, as in Herault et al. (2004); Younes and Simmons (2006); or require some specific knowledge of the system behavior, as in Sen et al. (2005); Rabih and Pekergin (2009).

In contrast, we introduce a new statistical method which automatically computes a bound \( k_0 \) on simulation path length and does not require any prior knowledge of the system. The central theme of our technique is to reduce the problem of verifying \( (\varphi_1 \mathcal{U} \varphi_2) \) to that of its

\(^1\)Gruniske (2008) proposes patterns for specifying probabilistic properties where he discusses the need for (time-) unbounded until properties for representing various probabilistic properties, e.g., invariance, existence, response.
bounded counter-part ($\varphi_1 U^k \varphi_2$). The reduction is possible only when a suitable $k_0$ can be obtained for which $P(s, \varphi_1 U^k \varphi_2)$ (i.e., the probability of satisfying of $\varphi_1 U^k \varphi_2$ at state $s$) is a good approximation of $P(s, \varphi_1 U \varphi_2)$. In other words, the bound $k_0$ is large enough to make the difference between $P(s, \varphi_1 U^k \varphi_2)$ and $P(s, \varphi_1 U \varphi_2)$ small. Such a $k_0$ provides an approximate upper bound of the sample path length needed for our statistical verification technique. We obtain $k_0$ using the probability of satisfying a different bounded path property: $\psi_k := (\varphi_1 U^k \varphi_2) \lor (\neg \varphi_2 U^k (\neg \varphi_1 \land \neg \varphi_2))$. This property states that the original property ($\varphi_1 U \varphi_2$) is either satisfied (first disjunct) or unsatisfied (second disjunct) in at most $k$ steps. We prove that a suitable $k_0$ is one for which $P(s, \psi_{k_0})$ is close to 1, and that the degree of “closeness” is related to $\epsilon$, the overall measure of accuracy of the entire statistical method.

In essence, there are two phases in our method. The first phase estimates $P(s, \psi_k)$ for $k = 0, 1, 2, \ldots$ and chooses $k_0$ which satisfies $P(s, \psi_{k_0}) \geq 1 - \epsilon_0$, where $\epsilon_0 < \epsilon$. In the second phase, $P(s, (\varphi_1 U^{k_0} \varphi_2))$ is estimated, which in turn serves as an estimate of $P(s, (\varphi_1 U \varphi_2))$. The computations for each phase involve only bounded-path properties and can be carried out efficiently using the existing sampling techniques such as those described in Herault et al. (2004). For systems where $P(s, \psi_k) \gneq 1 - \epsilon_0$ for any $k$, we propose an alternate heuristic method to estimate $P(s, (\varphi_1 U \varphi_2))$ based on changes in the estimates of $P(s, \psi_k)$ with $k$. 

Figure 1.1 A simple example.
1.1 Illustrative Example

To provide an intuitive explanation of why the proposed technique is useful and effective, we present a simple toy example (Figure 1.1) where the proposed method is applied successfully and where both the numerical method and the existing statistical verification method as implemented in the popular PRISM model checker (described in Hinton et al. (2006)) fail. The example contains a probabilistic transition system containing $6 + n$ states where $n$ is some large integer. The state $s_0$ is the start state of the system. The dotted segment in the figure represents some “complicated” transition structure on $n$ different states (see Jennings et al. (2010) for the specification). We will refer to this segment as $DS$. Let proposition $\varphi_1$ hold in all states except $s_2$ and $s_5$, and proposition $\varphi_2$ hold in states $s_3$ and $s_4$. The objective is to find the probability of satisfying the property $(\varphi_1 \cup \varphi_2)$ at state $s_0$. From the probabilities specified in the figure, we know that the resultant probability is 0.66 as there are only two paths $(s_0, s_3, \ldots)$ and $(s_0, s_4, \ldots)$ that satisfy the property.

We experimented with the PRISM model checker Hinton et al. (2006) using the above example. PRISM’s numerical method fails as the large state-space (large $n$) results in state-space explosion. PRISM’s statistical method takes a parameter $\epsilon$ as input and provides an approximate result within an $\epsilon$ error margin. Our experiments with several $\epsilon > 0$ failed to provide any estimate. This is because PRISM’s statistical method requires that the satisfaction of a property $\varphi_1 \cup \varphi_2$ be known within some pre-specified number of steps. The failure happens when at least one sample path enters $DS$ and does not leave $DS$. In this case, $\varphi_1$ is satisfied for all states in the path, but $\varphi_2$ is not satisfied for any states in the path, i.e., it cannot be known whether $\varphi_1 \cup \varphi_2$ is satisfied or not.

In terms of $\psi_k$ as introduced earlier, the above requirement in PRISM’s statistical method is equivalent to $P(s_0, \psi_k) = 1$, for some pre-specified bound $k$ ($k = 10,000$ by default in PRISM). In general, it is not possible to find an appropriate value for $k$ such that $P(s_0, \psi_k) = 1$. In contrast, we claim that it is not necessary to verify whether $P(s_0, \psi_k)$ is equal to 1. The necessary precision for an approximate statistical model checking can be obtained by identifying a $k$ ($k_0$ in our terminology) for which $P(s_0, \psi_k)$ is close to 1. In the above example, such a
bound can be immediately obtained as the sample paths \((s_0, s_1, \ldots)\) have very low probability \((\leq 0.01)\). Once such a bound is obtained, we compute \(P(s_0, \varphi_1 \cup \leq k_0 \varphi_2)\) which approximately coincides with \(P(s_0, \varphi_1 \cup \varphi_2)\). In our experiments, with \(n \approx 10^8\), the PRISM model checker fails to provide any result, while our method identifies a bound \(k_0 = 3343\) and estimates the probability to be equal to 0.6601 in approximately 97 seconds.

### 1.2 Contributions

The contributions of our approach are summarized as follows:

1. **Automation.** We present a methodology for automatically selecting a suitable bound \(k_0\) which allows unbounded until properties for probabilistic systems modeled as Discrete Time or Continuous Time Markov Chains to be verified using the corresponding \(k_0\)-bounded until properties. The reduction allows us to re-use the existing results for statistical verification of bounded until properties to identify the bound on the sample size \(N\) required to infer results within a pre-specified error margin.

2. **Universal Application.** The technique is applied for probabilistic model checking of any unbounded (untimed) path properties (expressed in PCTL or CSL) for models expressed as DTMC and CTMC.

3. **Theoretical Correctness.** We prove the soundness of our technique and discuss the condition under which our technique will always terminate with an estimate with a pre-specified error bound and confidence parameter. When the required condition is not satisfied in a system, our technique (as well as any other statistical method for probabilistic model checking that does not require prior knowledge of the complete model structure) will fail to terminate. We discuss a heuristic for dealing with such systems.

4. **Effective Implementation and Usability.** We present PRISM-U2B, an optimized implementation of our method based on the well-developed probabilistic model checking tool PRISM. We leverage PRISM’s realization of generating sample simulations from a given
DTMC or CTMC model and re-use PRISM’s widely-used graphical user interface, command-line interface and input specification languages, thereby reducing the cognitive burden of understanding and using PRISM-U2B. It is worth mentioning that Jansen et al. (2007) rates PRISM as the most user-friendly tool for probabilistic model checking in terms of modeling features and usability. Being based on PRISM, our tool PRISM-U2B enjoys similar ease of use.

5. Experimental Evaluation. We compare PRISM-U2B and PRISM’s statistical method, and empirically show that PRISM-U2B is about 1.5 times faster than PRISM for the examples where both can compute an estimate. We discuss several examples (and present results) where PRISM fails to provide an estimate while PRISM-U2B successfully terminates with an estimate. We also compare the tools PRISM-U2B and MRMC. MRMC is faster than PRISM-U2B as MRMC, unlike PRISM-U2B, utilizes pre-analysis of the model. However, MRMC fails for case studies with large state-space, where PRISM-U2B successfully computes the result. The tool PRISM-U2B, as well as its documentation and case studies\(^2\) can be obtained at Jennings et al. (2010).

1.3 Organization

Chapter 2 provides a brief overview of discrete time Markov chains and the probabilistic temporal logic PCTL. Chapter 3 discusses related work. Chapter 4 presents our solution methodology and its proof of correctness. The implementation is discussed in Chapter 5. Chapter 6 discusses the necessary condition for the termination of our technique and presents a heuristic method when this condition is not satisfied. Chapter 7 discusses the application of our technique for continuous time Markov chains. Chapter 8 presents a brief summary of the tool PRISM-U2B followed by its empirical evaluation using several examples in Chapter 9. Finally, Chapter 10 concludes with the summary and future avenues of research.

CHAPTER 2 Preliminaries

We proceed with a brief summary on probabilistic systems modeled as DTMC followed by the syntax and semantics of probabilistic properties expressed in the logic of PCTL. The proposed method and its explanations and theoretical results will be presented in terms of these concepts. Subsequently, we will show (Chapter 7) that the proposed method is equally applicable for specific types of reachability properties in CTMC.

2.1 Probabilistic Systems: Discrete Time Markov Chain Models

We will describe the behavior of a system that evolves from one configuration to another based on a certain probability as a state machine augmented with probabilities labeling the transitions. In its simplest form, where every transition in the state machine represents probabilistic choice and every choice only depends on the current configuration, the representation aligns with the definition of a DTMC.

**Definition 1.** A Discrete Time Markov Chain is defined as $\text{DTMC} = (S, s_I, T, L)$, where:

- $S$ is a finite set of states
- $s_I \in S$ is the initial or start state
- $T : S \times S \rightarrow [0, 1]$ is a transition probability function such that $\forall s : \sum_{s' \in S} T(s, s') = 1$
- $L : S \rightarrow \mathcal{P}(AP)$ is the labeling function which labels each state with a set of atomic propositions $\subseteq AP$ that hold in that state.

**Paths and Probability Measures.** A path in a DTMC, denoted by $\pi$, is a finite or infinite sequence of states $(s_0, s_1, s_2, s_3, \ldots)$ such that for all $i \geq 0 : s_i \in S$ and $T(s_i, s_{i+1}) > 0$. We denote
the set of all infinite paths starting from $s$ as $\text{Path}(s)$. $\pi[i]$ denotes the $i$-th state in the path $\pi$ and $|\pi|$ is the length of $\pi$ in terms of the number of transitions in $\pi$. For example, for an infinite path $\pi$, $|\pi| = \infty$, while for a finite path $\pi = (s_0, \ldots, s_n)$, $|\pi| = n, n \geq 0$. The cylinder set, denoted by $C_s(\pi)$ for a state $s$ and a finite length path $\pi$ starting from $s$, is defined as $C_s(\pi) = \{\pi' : \pi' \in \text{Path}(s) \land \pi \text{ is prefix of } \pi'\}$. Essentially, $C_s(\pi)$ is the set of all infinite paths $\in \text{Path}(s)$ with the common finite length prefix $\pi$. For any finite path $\pi$ with $|\pi| = n$ we define

$$P(\pi) = \begin{cases} 1 & \text{if } n = 0 \\ T(\pi[0], \pi[1]) \times \ldots \times T(\pi[n-1], \pi[n]) & \text{otherwise} \end{cases}$$

For a cylinder $C_s(\pi)$, define $Pr(C_s(\pi)) = P(\pi)$. It is well-known that this probability measure $Pr(\cdot)$ extends uniquely over all sets in the relevant $\sigma$-algebra of path(s).

### 2.2 Probabilistic Properties

Properties of a DTMC can be expressed using PCTL, an extension of standard CTL augmented with probabilistic specifications. Let $\varphi$ represent a state formula and $\psi$ represent a path formula. Then PCTL syntax is defined as follows:

$$\varphi \rightarrow tt | a \in AP | \neg \varphi | \varphi \land \varphi | P_{r}(\psi) \quad \text{and} \quad \psi \rightarrow \varphi U \varphi | \varphi U^{\leq k} \varphi$$

In the above, $\succ r \in \{\leq, \geq, <, >\}$, $r \in [0, 1]$ and $k \in \{0, 1, \ldots\}$. Note that we always use state formulas to specify the properties of a DTMC and path formulas only occur inside $P_{r}(\cdot)$. A state $s$ (or a path $\pi$) satisfying a state formula $\varphi$ (or a path formula $\psi$) is denoted by $s \models \varphi$ (or $\pi \models \psi$), and is inductively defined as follows:

- $s \models tt$ for all $s \in S$
- $s \models a \iff a \in L(s)$
- $s \models \neg \varphi \iff s \not\models \varphi$
- $s \models \varphi_1 \land \varphi_2 \iff s \models \varphi_1$ and $s \models \varphi_2$
- $s \models P_{r}(\psi) \iff \forall s, \psi \models P(s, \psi) \oplus r$

In the above, $P(s, \psi) = Pr(\{\pi \in \text{Path}(s) : \pi \models \psi\})$. In other words, $s \models P_{r}(\psi)$ holds if and only if the probability that $\psi$ is true for an outgoing infinite path from state $s$ is $\succ r$. For any infinite path $\pi$:

$$\pi \models \varphi_1 U^{\leq k} \varphi_2 \iff \exists 0 \leq i \leq k : \pi[i] \models \varphi_2 \land \forall j < i : \pi[j] \models \varphi_1$$

$$\pi \models \varphi_1 U \varphi_2 \iff \exists i \geq 0 : \pi[i] \models \varphi_2 \land \forall j < i : \pi[j] \models \varphi_1$$
Note that $\varphi_1 \mathbin{\bigvee} \varphi_2 \equiv \exists k : \varphi_1 \mathbin{\bigvee}^k \varphi_2$. We refer to properties of the form $\varphi_1 \mathbin{\bigvee} \varphi_2$ as unbounded because the bound $k$ is not fixed and not known a priori.
CHAPTER 3  Related Work

Legay and Delahaye (2010) survey and compare different probabilistic model checking techniques based on statistical sampling. In this section, we elaborate on some of these existing techniques and distinguish the contributions of our technique and those of the existing ones. We proceed with an overview of sampling based methods for probabilistic model checking.

Note that for all of these methods, it is necessary to decide whether a simulation path satisfies or does not satisfy the given property $\psi$. For a bounded path property $\psi = \varphi_1 \mathcal{U}^k \varphi_2$, simulation paths of length at most $k$ definitely satisfy or do not satisfy the property. For an unbounded path property $\psi = \varphi_1 \mathcal{U} \varphi_2$, it is not possible to know a priori the path length that is necessary to decide whether or not a given path satisfies $\psi$. In the following discussion, it is assumed that samples can be taken from the system. This implies that only bounded properties can be considered, or that some method exists that can determine the appropriate bound. The different methods to determine the bound (or to determine when to stop sampling) are discussed with each theoretical result.

3.1  Sampling Based Methods for Probabilistic Model Checking

The verification problem of whether a DTMC satisfies a probabilistic temporal property expressed in PCTL (Chapter 2) can be reduced to the problem of solving a set of linear equations over a set of variables where each variable corresponds to the probability that a state in the DTMC satisfies the given temporal (path) property. As mentioned before, this method of verification by solving linear equations numerically is referred to as the numerical method for probabilistic model checking (Hansson and Jonsson (1994); Bianco and de Alfaro (1995); Courcoubetis and Yannakakis (1995); Aziz et al. (2000); Baier et al. (2003)). However, as in traditional model
checking, the numerical method suffers from state-space explosion because it requires complete knowledge of the model state space. Furthermore, it is not possible to apply numerical methods in situations where the model transition structure is not available, but rather only simulation runs of the model can be obtained as needed (e.g. black-box systems).

To address the problem of state-space explosion and avoid the necessity of prior complete knowledge of the model transition structure, sampling based methods have been proposed and developed. The central theme of these methods is to infer from sample simulations whether the probabilistic property is satisfied by the model, while controlling the error in the inference using statistical bounds. In this context, there are two related inferencing methods: in one, the inference involves estimating the probability with which a state satisfies a property, while in the other, the inference involves verifying (accepting, or more precisely, rejecting) whether the probability that a state satisfies a property is greater (or less) than a pre-specified value. The former computes the estimate within certain confidence bounds (defined by error limits), while the latter employs hypothesis testing with an indifference width (interval where the null hypothesis and its alternate remain undecided). Both methods aim to obtain results such that the error in the result can be controlled. The methods use sample simulations associated to random variables $X_1, X_2, \ldots$ with outcomes of 1 or 0 depending on whether the simulation satisfies the path property or not; $X_i$ corresponds to the outcome of the $i$-th simulation. The proportion

$$\hat{p} = p_N = \frac{\sum_{i=1}^{N} X_i}{N}$$  \hspace{1cm} (3.1)

is used in both the statistical estimation and the hypothesis testing methods as an estimate of the probability that a property is satisfied.

Since it takes some time to obtain each sample, a secondary goal in any statistical method is to minimize $N$, which is the number of samples required. Intuitively, taking more samples increases confidence in the result of the test; however, different procedures can achieve the same confidence levels for varying values of $N$, as shown below.
3.1.1 Hypothesis Testing Based Statistical Estimation

Hypothesis based statistical estimation tests whether the probability that \( s \) satisfies \( \psi \) is \( \succ r \), where the probabilistic property under consideration is \( P_{\succ r}(\psi) \). For the discussion here, assume that \( \succ \) is \( \geq \). In this setting, the null hypothesis \( H_0 : p \geq r \) and its alternate \( H_1 : p < r \) are considered. For some number \( N \) of sample simulations starting from \( s \), the proportion of paths \( \hat{p} \) (Equation 3.1) that satisfy \( \psi \), is computed. The test rejects the null hypothesis if the proportion is less than \( r \), and does not reject the null hypothesis if the proportion is greater than or equal to \( r \). There are two types of errors considered in such a testing procedure. Type I error (false negative error) is the probability that the null hypothesis is rejected when in reality it holds. Type II error (false positive error) is the probability that the null hypothesis is not rejected when in reality it does not hold. The maximal bounds on these probabilities are typically denoted by \( \alpha \) and \( \beta \), i.e.,

\[
Pr[\text{Type I error}] = Pr[\text{reject } H_0 \mid H_0 \text{ holds}] \leq \alpha \\
Pr[\text{Type II error}] = Pr[\text{do not reject } H_0 \mid H_0 \text{ does not hold}] \leq \beta
\]

From the above, it can be shown that \( Pr[\text{do not reject } H_0 \mid H_0 \text{ holds}] \geq 1 - \alpha \). This implies that the test can correctly distinguish between the two cases \( p = r \) and \( p = r - \delta \) for some infinitesimally small delta, which in turn, requires that the samples cover the entire model (Younes and Simmons (2002)).

In order to overcome this deficiency, some tolerance (denoted \( \xi \)) must be introduced such that the test is not required to distinguish between infinitesimally small probabilities. The new test uses the hypothesis \( H'_0 : p \geq r + \xi \) and the alternate \( H'_1 : p \leq r - \xi \). Note that if the new test fails to reject \( H'_0 \) then it fails to reject \( H_0 \). Proceeding as before, let

\[
Pr[\text{reject } H'_0 \mid H'_0 \text{ holds}] \leq \alpha \\
Pr[\text{do not reject } H'_0 \mid H'_0 \text{ does not hold}] \leq \beta
\]

Therefore, \( Pr[\text{do not reject } H_0 \mid H'_0 \text{ holds}] \geq 1 - \alpha \), and \( Pr[\text{do not reject } H_0 \mid H'_1 \text{ holds}] \leq \beta \).

Consider \( p \) such that \( p = r \). Then this new test must fail to reject both \( H'_0 \) and \( H'_1 \). Therefore, this procedure can only be correctly applied for \( p \notin [r - \xi, r + \xi] \). This region is
(a) Performance of an ideal testing procedure. (b) Performance of a testing procedure with an indifference region.

Figure 3.1 Probability \(L_p\) of accepting the hypothesis \(p \geq \theta\).

referred to as the *indifference region*, and \(2\xi\) is called the indifference width. In effect, the probability of rejecting a true hypothesis cannot be bounded in this region. Younes (2005a) provides figures 3.1(a) and 3.1(b) to illustrate the concept of the indifference region.

Younes (2005a) describes several techniques for calculating the appropriate sampling size \(N\), which is a function of \(\alpha\), \(\beta\) and \(\xi\). The simplest is the single sampling plan. For some number of samples \(n\), compute the number of “successful” trials, defined by \(C = \sum_{i=1}^{n} X_i\). Then for some pair \(\langle c, n \rangle\), if \(c \geq \sum_{i=1}^{n} X_i\), reject \(H_1\); otherwise, reject \(H_0\). The challenge is to minimize \(n\) so that there exists some integer \(c\) such that this procedure will incorrectly reject \(H_0\) with probability at most \(\alpha\), and incorrectly reject \(H_1\) with probability at most \(\beta\).

Since \(C\) is the sum of a series of Bernoulli trials, \(C\) has a binomial distribution. The cumulative distribution function for the binomial distribution is given by:

\[
F(c; n, p) = P r(C \leq c) = \sum_{i=1}^{c} \binom{n}{i} p^i (1 - p)^{n - i} \tag{3.2}
\]

The goal is to select \(c\) and \(n\) such that

\[
\sum_{i=1}^{c} \binom{n}{i} p^i (1 - p)^{n - i} \leq \alpha \tag{3.3}
\]

and
\[ 1 - \sum_{i=1}^{c} \binom{n}{i} p^i (1 - p)^{n-i} \leq \beta \] (3.4)

There exist infinitely many \((c, n)\) pairs that satisfy these inequalities. Since the goal is to minimize the number of samples required, the pair with the smallest \(n\) should be selected. In general, there is no simple solution for these equations. Grubbs (1949) provides tables of values for various parameters. Younes (2005a) provides a binary search algorithm that can find these values for arbitrary parameters, and provides an approximation for \(n\) given \(\alpha\), \(\beta\), and \(\xi\). The sample size is inversely proportional to \((2\xi)^2\), and directly proportional to \(\log(\alpha)\) and \(\log(\beta)\). Therefore, it is generally more efficient to decrease \(\alpha\) and \(\beta\) than to decrease the indifference width.

A minor variation of the single sampling plan stops the testing as soon as \(c\) successful or \(n - c\) unsuccessful trials have been observed, since the remaining samples cannot change the final result.

The second major technique for determining \(N\) is based on the sequential probability ratio test, originally developed by Wald (1945). This test proceeds one sample at a time maintains a count of successful and unsuccessful trials. At each step, two quantities are computed: the probability of the observed sequence given that the true probability is less than \(p - \xi\) and the probability of the observed sequence given that the true probability is greater than \(p + \xi\). The ratio of these two quantities is compared to two values \(A\) and \(B\), which are defined such that \(0 < B < A\). If the ratio is less than or equal to \(B\), then \(H_1\) is rejected; if the ratio is greater than or equal to \(A\), then \(H_0\) is rejected. Otherwise, the test proceeds to the next sample.

\(A\) and \(B\) must be chosen appropriately such that \(H_0\) is incorrectly rejected with probability at most \(\alpha\) and \(H_1\) is incorrectly rejected with probability at most \(\beta\). In practice, Wald (1945) suggests defining \(A = \frac{1-\beta}{\alpha}\) and \(B = \frac{\beta}{1-\alpha}\), and demonstrates that these values give errors that are at most insignificantly greater than \(\alpha\) and \(\beta\).

The goal of this technique as opposed to the simple sampling plan is to reduce the number of samples required. Younes and Simmons (2006) shows that the expected number of samples is lower for the sequential probability ratio test, but can require a greater number of samples in
some cases. In practice, the sequential test is preferable because of the lower expected number of samples.

### 3.1.2 Implementations of hypothesis testing based approaches

#### 3.1.2.1 Ymer

Younes (2005b) describes a tool called Ymer that implements this method. Models are described using a variation of the PRISM modeling language and properties are expressed in either CSL for continuous time properties, or PCTL for discrete time properties. Younes et al. (2006) note that their method can handle unbounded until properties $\varphi_1 \cup \varphi_2$ only when any path in the model either reaches a deadlocked state or a state satisfying $\neg \varphi_1 \lor \varphi_2$. In its original implementation, Ymer does not support the unbounded until operator of either CSL or PCTL.

Recently, Younes et al. (2011) proposed two new methods for handling unbounded until properties. The first is based on reachability analysis and requires the construction of the full model before verification can proceed; therefore, it has similar memory requirements to the numerical method. Younes et al. (2011) shows empirically that this method is faster than the numerical method for large models.

The second method is based on a Monte Carlo method for inverting a matrix, developed by von Neumann and Ulam (published by Forsythe and Leibler (1950)). This method has a dependence on the subdominant eigenvalue of the transition matrix, which cannot be computed without building the full model. Younes et al. (2011) simplify the computation the subdominant eigenvalue for parametric models by computing it for small parameters and either using the same value for larger parameters, or adjusting it based on how it should change for the particular model. This approach is not practical for general models because they may not be parametric, or it may not be known how their subdominant eigenvalues scale. As this work is very recent, it is likely that the authors will extend this method to be more general in the future.
3.1.2.2 VESTA

Sen et al. (2005) introduce a new model checking algorithm based on hypothesis testing that can control both Type I and Type II errors. Given a path $\pi$ and a formula $\psi = \varphi_1 \mathbf{U} \varphi_2$, $\pi \models \psi$ if there exists some finite prefix of $\pi$ that ends with a state that satisfies $\varphi_2$. However, if $\pi \not\models \psi$ there is not necessarily some prefix $\pi$ that ends with a state that satisfies neither $\varphi_1$ nor $\varphi_2$. Rather, $\pi$ may contain states that satisfy only $\varphi_1$. In fact, there may be a strongly connected component in the model such that all states in the component satisfy $\varphi_1$ but not $\varphi_2$. The central observation of Sen et al. (2005) is that for any state $s$ in such a component, $P(s, \varphi_1 \mathbf{U} \varphi_2) = 0$.

Therefore, this technique defines a basis procedure which verifies $P(s, \varphi_1 \mathbf{U} \varphi_2) > 0$. For a model $M = (S, s_I, T, L)$, a new model $M' = (S', s_I, T', L')$ is constructed such that:

\[
S' = S \cup \{s_{\text{term}}\}
\]
\[
T'(t, s_{\text{term}}) = p_s \quad \forall t \in S
\]
\[
T'((s_{\text{term}}, s_{\text{term}})) = 1
\]
\[
T'(t, u) = T(t, u) \cdot (1 - p_s) \quad \forall t, u \in S
\]
\[
L'(s) = L(s) \quad \forall s \in S
\]
\[
L'(s_{\text{term}}) = \emptyset
\]

In effect, a new state $s_{\text{term}}$ is created such that all other states reach $s_{\text{term}}$ with probability $p_s$, and $s_{\text{term}}$ does not satisfy $\varphi_1 \mathbf{U} \varphi_2$. Here $p_s$ is some pre-specified probability that will be discussed in more detail later. In this modified model, for any path $\pi$, there exists an extension $\hat{\pi}$ such that $\pi \hat{\pi}$ is a valid path in the model, and the last state in $\hat{\pi}$ does not satisfy $\varphi_1 \mathbf{U} \varphi_2$. That is, starting from any state, there is a non-zero probability of sampling a state that satisfies either $\varphi_2$ or $\neg \varphi_1 \land \neg \varphi_2$. Note that this same statement cannot be said of the original model $M$ and that this property allows finite samples to be taken from the model $M'$.

The basis procedure samples paths from the modified model $M'$. If it ever samples a path that satisfies $\varphi_1 \mathbf{U} \varphi_2$, then $P(s, \varphi_1 \mathbf{U} \varphi_2) > 0$ for all states in the path (up to the state that satisfies $\varphi_2$). If it samples a large number of paths and never finds a path that satisfies $\varphi_1 \mathbf{U} \varphi_2$,
then \( P(P(s, \varphi_1 U \varphi_2) > 0) < \delta \) for some \( \delta \).

Unfortunately the basis procedure as described by Sen et al. (2005) is flawed, for two reasons.

First, the basis procedure depends on the parameters \( p_s \) and \( \delta_2 \). The algorithm requires that \( p > \frac{\delta_2}{(1-p_s)^N} \), where \( p = P(s, \varphi_1 U \varphi_2) \) and \( N \) is the number of states in the model. However, since \( p \) is the quantity that is desired to be computed, the user cannot appropriately determine a value for \( \delta_2 \).

Second, Sen et al. (2005) include a proof of the following theorem:

\[
p' \geq (1-p_s)^N \cdot p
\]

(3.5)

where \( p' \) is the probability that a path satisfies the property in \( M' \). This theorem effectively bounds the error from sampling from the modified model instead of sampling from the original model. Younes and Simmons (2006) note that the proof does not hold in general for models with loops.

In He et al. (2010), we propose an alternate to the basis procedure that is valid for any model. The alternate technique requires prior knowledge of the total number of states in the model and its maximum branching factor. The technique is similar to the one proposed by Grosu and Smolka (2005), which deals with sampling based model checking of non-probabilistic models against linear temporal logic (LTL) properties. In contrast to Grosu and Smolka (2005), the technique proposed in this paper does not depend on the state-space of the model and can be used to model check probabilistic properties of probabilistic models.

3.1.2.3 MRMC

Zapreev (2008) proposes a hypothesis testing based statistical technique for verifying unbounded until properties that also uses estimations based on confidence intervals (see Section 9.3 for details). This technique begins by identifying the bottom strongly connected components, or BSCCs, in the model. If a simulation path enters a BSCC and none of the states in the BSCC satisfy \( \varphi_1 U \varphi_2 \), then it is known that the path will never satisfy \( \varphi_1 U \varphi_2 \).
Therefore, sampling for this path can be terminated. The computation of the BSCCs requires preanalysis of the model, and thus limits the application of this technique. The tool MRMC, found at MRMC (2010), is based on Zapreev (2008). Katoen and Zapreev (2009) compare MRMC with Ymer and VESTA, and show that both Ymer and VESTA use less space (constant memory) than MRMC, while the verification times of MRMC are mostly several factors (up to 10) smaller than those of Ymer and VESTA. However, the performance of MRMC rapidly decreases with growth in model size. A similar and more detailed comparison is presented by Jansen et al. (2007).

3.1.2.4 Ψ²

For an ergodic DTMC with any starting distribution, after some number of steps, the probability distribution at the next state equals the probability distribution at the current state. In effect, the DTMC has a steady-state distribution. The number of steps required before the DTMC reaches the steady-state distribution is model dependent. Propp and Wilson (1996) describe a procedure that can calculate the appropriate number of steps through simulation. Rabih and Pekergin (2009) propose a new statistical approach to check both steady-state and unbounded until properties utilizing this procedure.

The key insight from Rabih and Pekergin (2009) is that if a sample path reaches the steady-state while always satisfying \( \varphi_1 \land \neg \varphi_2 \), then it will never reach a state that satisfies \( \varphi_1 \land \varphi_2 \). The knowledge of the steady-state distribution effectively allows sampling to be terminated at the appropriate time for any given path.

Rabih and Pekergin (2009) provide a tool called Ψ² (available at Rabih and Pekergin (2011)), which implements this method. They provide experimental results from the tool, but no comparison to other tools.

The major drawback of this method is that it requires that the model be ergodic (i.e. irreducible and aperiodic). This condition cannot be guaranteed in general, and determining whether a model is ergodic has space complexity polynomial to the model size and therefore can result in space-space explosion. This condition also precludes the application of this method for
models where it is impossible to verify ergodicity, such as black-box systems or other systems where knowledge of the transition structure is not available.

### 3.1.3 Confidence Interval Based Statistical Estimation

In contrast to the above approaches, these methods attempt first to compute an estimate of the probability \( p \) with which paths from \( s \) satisfy \( \psi \). Then (if desired), the estimate can be compared to the given bound to determine satisfaction of the property \( \psi \).

Given a state \( s \) in a \( \text{DTMC} \) and a path property \( \psi \), an appropriate number of samples, say \( N \), is obtained starting from \( s \); and \( \hat{p} \) (Equation 3.1) is used as the estimate of the probability \( p \) with which paths from \( s \) satisfy \( \psi \). The estimation method aims to bound the error in the estimate as follows:

\[
Pr(|\hat{p} - p| > \epsilon) < \delta
\]

In the above, \( \epsilon \) is the error bound of the estimate and \( \delta \) is the probability of error in the estimate, i.e., the probability that the estimate is at least \( \epsilon \) distance away from \( p \). \( \delta \) is also referred to as the confidence parameter of the estimate. The interval \([p - \epsilon, p + \epsilon]\) is referred to as the confidence interval. Given \( \epsilon \) and \( \delta \), one can use the Chernoff-Hoeffding inequality developed by Hoeffding (1963) to precisely compute the lower bound of the number of samples \( (N) \) for probabilistic model checking. Smaller values for \( \epsilon \) and \( \delta \) result in larger values of this lower bound.

Herault et al. (2004) have proposed a method to verify a subset of \( \text{LTL} \) formulae, namely the \textit{EPF} (Essentially Positive Fragment) in \( \text{DTMC} \). Their technique checks whether the probability that a state satisfies an unbounded path property \( \psi \) is greater than or equal to \( r \). This is performed using the null hypothesis \( H_0 : p \geq r \) against the alternate \( H_1 : p < r \). The technique relies on estimating \( p \) (Chapter 3.1.3) within a pre-specified error bound and uses the Chernoff-Hoeffding inequality (Hoeffding (1963)) to obtain the appropriate sample size. However, it fails to completely control the error in the procedure.

The sample path length used in the procedure has a pre-specified upper bound. If a simulation reaches that bound and fails to infer a decided result (i.e., whether the path satisfies
the given path property or not), the technique assumes that the simulation, if allowed to proceed, eventually will not satisfy the path property under consideration. This assumption allows the method to control Type II error within a pre-specified limit. However, as the authors state in Herault et al. (2004), the proposed technique cannot determine the appropriate upper bound on simulation path length to control the number of the undecided simulations. As such, the method loses control of Type I error (the error that the null hypothesis $H_0$ holds but the test rejects it).

### 3.1.4 Implementations of confidence interval based approaches

#### 3.1.4.1 APMC

Herault et al. (2006) describes a tool called APMC, or Approximate Probabilistic Model Checker. As noted above, the tool cannot control error for unbounded path properties. Herault et al. (2004) does not directly address this problem, other than to note that it is an issue.

#### 3.1.4.2 PRISM

After the development of APMC, the technique was incorporated in the popular probabilistic model checker PRISM, as described by Hinton et al. (2006). The distinguishing feature of PRISM’s statistical approach is that unlike the method described above, which allows undecided simulations, PRISM will not provide a result to the model checking problem if any sample path remains undecided for some arbitrary, pre-specified length. Although this feature effectively controls Type I error, it becomes necessary to identify a bound on sample length for which the simulation run of each sample will have a decided result. If a sample reaches this predetermined length, the simulation process is aborted and the user is requested to run the experiment again with a larger bound.

All of the results presented in this paper are based on PRISM 3.3.1 (released November 22, 2009). Recently, prerelease versions of PRISM 4 have become available. This new version of PRISM supports both confidence interval and hypothesis testing approaches. More discussion of PRISM 4 is included in Chapter 10.2.
3.1.4.3 PRISM-U2B

We propose herein a technique which can be viewed as a natural extension of the technique proposed by Herault et al. (2004) and the algorithm implemented in PRISM. It uses two phases: in the first phase, an appropriate system-dependent bound $k_0$ in sample length is obtained automatically; and in the second phase, this bound is used to compute the result for unbounded until properties. In effect, a property $\varphi_1 \mathcal{U} \varphi_2$ is converted into the property $\varphi_1 \mathcal{U}_{\leq k_0} \varphi_2$, while maintaining the desired error bounds. To the best of our knowledge, this is the first technique that can estimate the probability of satisfying unbounded until properties in probabilistic DTMC and CTMC models using statistical sampling without any prior knowledge of the model structure to appropriately control the error in estimate.

It should be noted that any of the existing techniques based on either confidence interval estimation or hypothesis testing could be deployed in the second phase of our technique, as the property under consideration is bounded appropriately by $k_0$, which is computed automatically in the first phase. The results presented here use the technique developed by Herault et al. (2006), as implemented in PRISM.

3.2 Summary

Table 3.2 provides a brief summary and comparison of the model checking tools presented here. The usability rankings are based on Jansen et al. (2007), with $\ldots$ indicating the lowest score, $++$ indicating the highest score, and 0 being neutral.

PRISM’s modeling language, which is based on the reactive modules formalism developed by Alur and Henzinger (1999), is considered to be the easiest to use. APMC imports PRISM models directly, while MRMC has the option of importing models exported from PRISM. Ymer uses a language similar to PRISM’s language.

Ψ² is a new tool created by Rabih and Pekergin (2009) to demonstrate the effectiveness of perfect sampling as applied to probabilistic model checking. As such, its modeling and usability scores are low.

Note that most of the tools either do not support unbounded until properties at all, do

Table 3.1 Comparison of model checking tools

<sup>a</sup>Partially based on Jansen et al. (2007)
<sup>b</sup>Incorrect results for models containing loops
<sup>c</sup>Requires knowledge of model (BSCC detection)
<sup>d</sup>Requires ergodic models
<sup>e</sup>Does not control Type I error
<sup>f</sup>Does not always provide a result

not provide correct results for unbounded until properties, or only support unbounded until properties in certain types of models. Only **PRISM-U2B** provides correct results for unbounded until properties in arbitrary models.
CHAPTER 4 Two-phase Approximate Probabilistic Model Checking

The objective of our work is to reduce unbounded until properties to bounded until properties in the context of probabilistic model checking. The main problem that needs to be addressed to realize such a reduction involves identifying

(a) a suitable bound $k_0$ for checking the bounded until property (in each simulation) (done in Phase I), and

(b) a bound on the number of simulation-paths (each of length $k_0$) (done in Phase II),

such that a statistical sampling based verification result of the bounded until property approximately coincides with that of the unbounded until property within a pre-specified error limit.

4.1 Rationale

The paths belonging to the semantics of $\varphi_1 U \varphi_2$ (Section 2.1) can be partitioned into two groups for each $k \geq 1$: one includes the paths that satisfy the property in $\leq k$ steps; while the other includes the paths that satisfy the property in $> k$ steps. I.e., the semantics of $\varphi_1 U \varphi_2$ can be written as

$$\pi \models \varphi_1 U \varphi_2$$

$$\Leftrightarrow \forall k : \left[ \exists 0 \leq i \leq k : \pi[i] \models \varphi_2 \land \forall j < i : \pi[j] \models \varphi_1 \right]$$

$$\vee$$

$$\left[ \exists i > k : \pi[i] \models \varphi_2 \land \forall j < i : \pi[j] \models \varphi_1 \land \neg \varphi_2 \right]$$

$$\Leftrightarrow \pi \models \forall k : \left[ (\varphi_1 U^{\leq k} \varphi_2) \lor (\varphi_1 U^{> k} \varphi_2) \right]$$
Note that we have defined that $\pi \models \varphi_1 U^k \varphi_2$ if and only if the first state $\pi[i]$ that satisfies $\varphi_2$ appears in $\pi$ after at least $k + 1$ steps and $\varphi_1$ is satisfied in all states before $\pi[i]$.

Since $(\varphi_1 U^k \varphi_2) \land (\varphi_1 U^k \varphi_2) = \mathsf{ff}$, by law of total probability

$$P(s, \varphi_1 U \varphi_2) = P(s, \varphi_1 U^k \varphi_2) + P(s, \varphi_1 U^k \varphi_2)$$  \hfill (4.1)

From the fact that probabilities $\in [0, 1]$,

$$0 \leq P(s, \varphi_1 U \varphi_2) - P(s, \varphi_1 U^k \varphi_2) = P(s, \varphi_1 U^k \varphi_2)$$  \hfill (4.2)

Next consider the property $\varphi_1 U^k \varphi_2$.

$$\pi \models \varphi_1 U^k \varphi_2$$
$$\Leftrightarrow \exists i > k : \pi[i] \models \varphi_2 \land \forall j < i : \pi[j] \models \varphi_1 \land \neg \varphi_2$$
$$\Rightarrow \forall i \leq k : \pi[i] \models \varphi_1 \land \neg \varphi_2$$
$$\Leftrightarrow \varphi_1 U \varphi_2 \text{ is neither satisfied nor unsatisfied in } k \text{ steps from } \pi[0]$$
$$\Leftrightarrow \pi \models \neg (\varphi_1 U^k \varphi_2) \land \neg (\neg \varphi_2 U^k (\neg \varphi_1 \land \neg \varphi_2))$$

Let $\psi_k = (\varphi_1 U^k \varphi_2) \lor (\neg \varphi_2 U^k (\neg \varphi_1 \land \neg \varphi_2))$, i.e., $\psi_k$ is the property that is satisfied by a path $\pi$ only when the satisfiability of $\varphi_1 U \varphi_2$ can be proved or disproved in $k$ steps from the start state ($\pi[0]$). Therefore, from the above, $(\varphi_1 U^k \varphi_2) \Rightarrow \neg \psi_k$ and

$$P(s, \varphi_1 U^k \varphi_2) \leq P(s, \neg \psi_k) = 1 - P(s, \psi_k)$$  \hfill (4.3)

From Equations 4.2 and 4.3, for any $k \geq 1$ we obtain

$$0 \leq P(s, \varphi_1 U \varphi_2) - P(s, \varphi_1 U^k \varphi_2) \leq 1 - P(s, \psi_k)$$  \hfill (4.4)

Our objective is to select a $k_0$ such that for any given $\epsilon_0$.

$$P(s, \psi_{k_0}) \geq 1 - \epsilon_0$$  \hfill (4.5)

In that case,

$$0 \leq P(s, \varphi_1 U \varphi_2) - P(s, \varphi_1 U^{k_0} \varphi_2) \leq 1 - P(s, \psi_{k_0}) \leq \epsilon_0$$  \hfill (4.6)

In other words, by choosing an appropriate $k_0$, the probability of satisfying the unbounded path property $\varphi_1 U \varphi_2$ can be made close (within an error margin of $\epsilon_0$, for any arbitrarily small choice of $\epsilon_0$) to the probability of satisfying the bounded path property $\varphi_1 U^{k_0} \varphi_2$. 
4.2 U2B: Two-phase Approximate Model Checking for DTMC

The discussion in the previous section (specifically, Equations 4.5 and 4.6) motivates our two phase method. In the first phase we determine a suitable $k_0$ and in the second phase we estimate $P(s, \varphi_1 \mathbf{U} \leq k_0 \varphi_2)$. Finally, we use this estimate of $P(s, \varphi_1 \mathbf{U} \leq k_0 \varphi_2)$ as the estimate of $P(s, \varphi_1 \mathbf{U} \varphi_2)$. Our method utilizes confidence interval based statistical estimation (see Section 3.1.3) in both phases.

In *Phase I*, $P(s, \psi_k)$ is estimated for different values of $k$ using $N_1$ Monte Carlo simulation paths similar to the GAA (Generic Approximation Algorithm) described in Herault et al. (2004). This is done for all $k \geq 1$ until for some $k_0$, the estimate satisfies Equation 4.5.

Once $k_0$ is obtained, in *Phase II* we estimate $P(s, \varphi_1 \mathbf{U} \leq k_0 \varphi_2)$. This estimate is computed as the proportion of $N_2$ Monte Carlo simulation paths (each of length at most $k_0$) that satisfy $\varphi_1 \mathbf{U} \leq k_0 \varphi_2$. This also can be thought of as a simple application of the GAA algorithm for bounded until properties described in Herault et al. (2004).

The two phases for computing $k_0$ and then computing $P(s, \varphi_1 \mathbf{U} \leq k_0 \varphi_2)$ are carried out “independently”, i.e., involving separate samples (of sizes $N_1$ and $N_2$ respectively), which enables us to combine the errors in two phases to guarantee a certain precision. The number of Monte Carlo simulation paths used in the two phases and the value of $k_0$ are chosen in a way that controls the errors in each of the phases and combines them to guarantee the correctness of the final estimate within a pre-specified error limit (see Theorem 1 below). In short, our method, $\text{U2B}(M, s, \varphi_1 \mathbf{U} \varphi_2, \epsilon, \delta)$, takes as input the DTMC model $M$, the state $s$, the until property under consideration, the error margin $\epsilon$ and the confidence parameter $\delta$; and returns the estimate of $P(s, \varphi_1 \mathbf{U} \varphi_2)$ within $\epsilon$ bound with a high degree of certainty (at least $1 - \delta$). The steps of our method are summarized as follows:

**Main Steps.** $\text{U2B}(M, s, \varphi_1 \mathbf{U} \varphi_2, \epsilon, \delta)$

1. **Phase I**: Obtaining $k_0$

   (a) Choose $N_1 \geq N_1^* = 9 \log(\frac{4}{\delta})/2\epsilon^2$. From $M$, obtain $N_1$ Monte Carlo simulation paths of length $k = 1$. For $i = 1, \ldots, N_1$, let $X_i = 1$ if the $i$-th simulation satisfies $\psi_k$;
\[ X_i = 0 \text{ otherwise.} \]

(b) Estimate \( P(s, \psi_k) \) as the proportion of the simulation paths satisfying \( \psi_k \), i.e.
\[
\hat{P}(s, \psi_k) = \frac{1}{N_1} \sum_{i=1}^{N_1} X_i. \tag{4.7}
\]

(c) Verify if Equation 4.5 is satisfied by the estimate in Equation 4.7 with the current value of \( k \) and \( \epsilon_0 = \frac{\epsilon}{3} \). More precisely, if
\[
\hat{P}(s, \psi_k) \geq 1 - \epsilon_0 = 1 - \epsilon/3, \tag{4.8}
\]

then \( k_0 = k \) and proceed to Phase II. Otherwise, increase \( k \) by 1 and generate one more transition for each of the existing \( N_1 \) simulation paths, creating \( N_1 \) paths of increased (by 1) length. Define \( X_i, i = 1, \ldots, N_1 \) as in Step 1(a) using these extended simulation paths and repeat the Step 1(b)-(c).

2. **Phase II**: Estimating \( P(s, \varphi_1 \cup^{k_0} \varphi_2) \)

(a) Choose \( N_2 \geq N_1^* = 36 \log(\frac{4}{\epsilon})/\epsilon^2 \). From \( M \), obtain \( N_2 \) Monte Carlo simulation paths (of length at most \( k_0 \)). For \( i = 1, \ldots, N_2 \), let \( Y_i = 1 \) if the \( i \)-th simulation path satisfies \( \varphi_1 \cup^{k_0} \varphi_2 \); \( Y_i = 0 \) otherwise.

(b) Estimate \( P(s, \varphi_1 \cup^{k_0} \varphi_2) \) as the proportion of the simulation paths that satisfy \( \varphi_1 \cup^{k_0} \varphi_2 \), i.e.
\[
\hat{P}(s, \varphi_1 \cup^{k_0} \varphi_2) = \frac{1}{N_2} \sum_{i=1}^{N_2} Y_i. \tag{4.9}
\]

Return \( \hat{P}(s, \varphi_1 \cup^{k_0} \varphi_2) \), as the estimate for \( P(s, \varphi_1 \cup \varphi_2) \)

### 4.3 Proof of Correctness

The following theorem states the correctness of our method.

**Theorem 1.** Given any precision parameter \( \epsilon > 0 \) and confidence parameter \( \delta > 0 \), the estimator \( \mathcal{U}_2B(M, s, \varphi_1 \cup \varphi_2, \epsilon, \delta) \) with the chosen values of \( k_0, N_1^*, N_2^* \) satisfies the following:
\[
Pr \left( \left| \mathcal{U}_2B(M, s, \varphi_1 \cup \varphi_2, \epsilon, \delta) - P(s, \varphi_1 \cup \varphi_2) \right| > \epsilon \right) \leq \delta. \tag{4.10}
\]
We begin by discussing auxiliary results in theoretical statistics that will be used in proving the above theorem. We discuss properties of the estimation procedure separately for the two phases.

4.3.1 Phase I: Estimating $k_0$

Let $F(\cdot)$ be a function where $F(k) = \mathbb{P}(s, \psi_k), k \geq 1$. Figure 4.1 illustrates the sample valuations of $F(\cdot)$ for different valuations of $k$; we refer to this graph as the *Decided Graph* (D-Graph); $F(k)$ being the probability that $\varphi_1 U \varphi_2$ is decided in $\leq k$ steps from the state $s$. The main challenge in Phase I is that the function $F(\cdot)$ is not typically known. If this function were known, finding a $k_0$ that satisfies Equation 4.5 could have been achieved by simply inverting this (non-decreasing) function.

The function $F(\cdot)$ can be thought of as the cumulative distribution function (c.d.f) of a random variable $K = \text{the minimum number of transitions required to verify } \varphi_1 U \varphi_2 \text{ along a randomly selected simulation path in the given model}$. In this way, our estimation process in Phase I is equivalent to estimating this c.d.f using $N_1$ independent samples collected from the distribution of this variable $K$. In fact, our estimate $\hat{\mathbb{P}}(s, \psi_k)$ (as a function of $k$) is the usual empirical c.d.f estimator $\hat{F}_{N_1}(\cdot)$ of the true c.d.f $F(\cdot)$. It is well known that $k \geq 1, \hat{F}_{N_1}(k)$ converges to $F(k)$, as $N_1 \to \infty$ at a suitable rate, for each $k$. For the proof of Theorem 1, we need the rate *uniform* in $k$ at which this convergence takes place. This is provided by the
celebrated Dvoretzky-Kiefer-Wolfowitz (DKW) inequality (see for example, Massart (1990)): For each \( \epsilon_1 > 0, N_1 \geq 1 \), \( \Pr \left( \sup_{k \geq 1} \left| \hat{F}_{N_1}(k) - F(k) \right| > \epsilon_1 \right) \leq 2 e^{-2N_1(\epsilon_1)^2} \). This result, restated in terms of \( P(s, \psi_k) = F(k) \) and \( \hat{P}(s, \psi_k) = \hat{F}_{N_1}(k) \), for each \( k \), yields the following lemma, which will be needed for our proof of Theorem 1.

**Lemma 1.** Given any \( \epsilon_1 > 0 \) and \( N_1 \geq 1 \),
\[
\Pr \left( \sup_{k \geq 1} \left| \hat{P}(s, \psi_k) - P(s, \psi_k) \right| > \epsilon_1 \right) \leq 2 e^{-2N_1(\epsilon_1)^2}.
\]

### 4.3.2 Phase II: Estimating \( P(s, \varphi_1 \ U^{\leq k_0} \ \varphi_2) \)

In this phase, we estimate the probability of the bounded until property \( \varphi_1 \ U^{\leq k_0} \ \varphi_2 \) in \( M \), with \( k_0 \geq 1 \) as determined in Phase I. For any given \( k \geq 1 \), our algorithm in Phase II is simply the GAA algorithm (c.f. Herault et al. (2004)) of estimating the probability of a bounded until property \( \varphi_1 \ U^{\leq k} \ \varphi_2 \) in \( M \). Hence using the same technique (i.e., using Chernoff-Hoeffding bound) we get for each \( \epsilon_2 > 0 \),
\[
\Pr \left( \left| \hat{P}(s, \varphi_1 \ U^{\leq k} \ \varphi_2) - P(s, \varphi_1 \ U^{\leq k} \ \varphi_2) \right| > \epsilon_2 \right) \leq 2 e^{-N_2(\epsilon_2)^2/4}.
\]

Now since the above inequality is true for all \( k \geq 1 \), it is true conditional on the simulations of Phase I, for \( k = k_0 \). But the two phases are carried out independently, which means the above statement must be true unconditionally as well, for \( k = k_0 \). Summarizing this discussion, we have

**Lemma 2.** Given any \( \epsilon_2 > 0 \) and \( N_2 \geq 1 \), for \( k_0 \) given by Phase I of \( U2B \)
\[
\Pr \left( \left| \hat{P}(s, \varphi_1 \ U^{\leq k_0} \ \varphi_2) - P(s, \varphi_1 \ U^{\leq k_0} \ \varphi_2) \right| > \epsilon_2 \right) \leq 2 e^{-N_2(\epsilon_2)^2/4}.
\]

Now we use the results of Lemmas 1 and 2 to complete the proof of Theorem 1.

**Proof of Theorem 1.** The triangle inequality (after adding and subtracting suitable terms) yields the following
\[
\left| \mathbb{U}2B(M, s, \varphi_1 \ U \ \varphi_2, \epsilon, \delta) - P(s, \varphi_1 \ U \ \varphi_2) \right| = \left| \hat{P}(s, \varphi_1 \ U^{\leq k_0} \ \varphi_2) - P(s, \varphi_1 \ U \ \varphi_2) \right| \\
\leq \left| \hat{P}(s, \varphi_1 \ U^{\leq k_0} \ \varphi_2) \right| - \left| P(s, \varphi_1 \ U^{\leq k_0} \ \varphi_2) \right| + \left| P(s, \varphi_1 \ \varphi_2) \right| - \left| P(s, \varphi_1 \ U^{\leq k_0} \ \varphi_2) \right|.
\] (4.11)
Recall from Equation 4.8 that we have \( 1 - \hat{P}(s, \psi_k) \leq \epsilon/3 \). Hence, using Equation 4.4 and the triangle inequality, we get the following bound on the last term in Equation 4.11

\[
| P(s, \varphi_1 \cup \varphi_2) - P(s, \varphi_1 \cup \varphi_2^k) | \leq (1 - P(s, \psi_{k_0}))
\]

\[
\leq (1 - \hat{P}(s, \psi_{k_0})) + | \hat{P}(s, \psi_{k_0}) - P(s, \psi_{k_0}) |
\]

\[
\leq \frac{\epsilon}{3} + \sup_{k \geq 1} \left| \hat{P}(s, \psi_k) - P(s, \psi_k) \right|.
\]  

(4.12)

Combining Equation 4.11 with Equation 4.12, we get the following bound

\[
| U2B(M, s, \varphi_1 \cup \varphi_2, \epsilon, \delta) - P(s, \varphi_1 \cup \varphi_2) | \leq
\]

\[
| \hat{P}(s, \varphi_1 \cup \psi_{k_0} \varphi_2) - P(s, \varphi_1 \cup \psi_{k_0} \varphi_2) | + \frac{\epsilon}{3} + \sup_{k \geq 1} \left| \hat{P}(s, \psi_k) - P(s, \psi_k) \right|
\]

Hence, the fact that the left side of the above inequality is greater than \( \epsilon \) (see Equation 4.10 in Theorem 1) implies that at least one of the terms on the right side is greater than \( \epsilon/3 \).

Therefore, we obtain the following:

\[
Pr \left( | U2B(M, s, \varphi_1 \cup \varphi_2, \epsilon, \delta) - P(s, \varphi_1 \cup \varphi_2) | > \epsilon \right)
\]

\[
\leq Pr \left( | \hat{P}(s, \varphi_1 \cup \psi_{k_0} \varphi_2) - P(s, \varphi_1 \cup \psi_{k_0} \varphi_2) | > \frac{\epsilon}{3} \right)
\]

\[
+ Pr \left( \sup_{k \geq 1} \left| \hat{P}(s, \psi_k) - P(s, \psi_k) \right| > \frac{\epsilon}{3} \right) \leq \delta.
\]  

(4.13)

The last inequality follows from the bounds in Lemmas 1 and 2 with \( \epsilon_1 = \epsilon/3 \) and \( \epsilon_2 = \epsilon/3 \), since with \( N_i \geq N_i^* \), \( i = 1, 2 \), we have \( 2e^{-2N_i(\epsilon_1)^2} \leq \delta/2 \) (i.e., \( N_1 \geq \frac{1}{4\epsilon^2} \log \left( \frac{1}{\delta} \right) \geq \frac{9}{2 x^2 \log \left( \frac{4}{3} \right)} \)) and \( 2e^{-N_2(\epsilon_2)^2/4} \leq \delta/2 \) (i.e., \( N_2 \geq \frac{4}{e^2} \log \left( \frac{4}{3} \right) \geq \frac{36}{e^2} \log \left( \frac{4}{3} \right) \)). This completes the proof of Theorem 1.

\[ \square \]

**Remark 1.** Observe that there are three error bounds that are derived from \( \epsilon \), each of which is assigned to \( \frac{\epsilon}{3} \): \( \epsilon_0 \) (From Equation 4.8), \( \epsilon_1 \) (From Lemma 1) and \( \epsilon_2 \) (From Lemma 2). While \( \epsilon_0 \) is the measure of closeness of \( \hat{P}(s, \psi_k) \) to 1, \( \epsilon_1 \) and \( \epsilon_2 \) capture the closeness of the estimated and true probabilities in each phase. In other words, a smaller \( \epsilon_0 \) will lead to a larger value for \( k_0 \) (sample path length), while smaller \( \epsilon_1 \) and \( \epsilon_2 \) values will result in larger values for \( N_1 \) and \( N_2 \), the sample sizes in each phase. The proof of our theorem holds as long as \( \epsilon_0 + \epsilon_1 + \epsilon_2 = \epsilon \). These values can be fine tuned experimentally.
CHAPTER 5 Efficient & Practical Realization of U2B Model Checker

As discussed in Section 4.2, our method, U2B, involves two phases. In this chapter, we present a direct (naive) implementation of Phase I followed by an optimized variation. Recall that Phase II deals with estimating $P(s, \varphi_1 U^{k_0} \varphi_2)$, which can be immediately computed using the existing statistical method present in PRISM; as such, we do not provide any additional optimization for Phase II. The integration of this method into PRISM (i.e. the development of PRISM-U2B) is discussed in Chapter 8.

5.1 Naive Implementation of Phase I

Algorithm 1 lists the procedure IDENTIFYK0, describing a naive realization of Phase I in U2B. workingSet contains the set of current states (last states of simulation paths) that are examined in Phase I. It is initialized with $N_1$ copies of the start state of the model; these are the current states in $N_1$ paths of length 0 (Line 3). The variable trueCount, initialized to 0 (Line 4), captures the number of paths in workingSet that satisfy $\psi_k$.

The states in workingSet are verified to check whether $\psi_k$ is satisfied; if satisfied, the states are removed from workingSet and trueCount is incremented (Lines 6–9). Observe that trueCount captures the number of paths of length $k$ that satisfy $\psi_k$. Therefore, trueCount/$N_1$ computes $\hat{P}(s, \psi_k)$ (Equation 4.7). The loop (Lines 5) is terminated if $N_1(1 - \epsilon_0) \leq$ trueCount (Lines 10, 11), i.e., if the proportion of paths in the sample of size $N_1$ that satisfy $\psi_k$ is less than $1 - \epsilon_0$.

If the terminating condition is not satisfied, $k$ is incremented and workingSet is updated by obtaining the next states of the paths in the working set by random selection based on the probability distribution in the model. On termination of the iteration, i.e., when
Algorithm 1 Naive Implementation of Phase I

\begin{algorithm}
\begin{algorithmic}[1]
\Procedure{identifyK0}{$N_1, \epsilon_0, \psi$}
\State $N_1$: Total number of samples for Phase I (see U2B Step 1(a))
\State $\epsilon_0$: closeness to 1 (see U2B Step 1(c))
\State $\psi := (\varphi_1 \lor \varphi_2) \lor (\neg \varphi_2 \lor \neg \varphi_1 \land \neg \varphi_2)$
\State $k := 0$
\State workingSet := add $N_1$ copies of start state; \Comment{path length $k = 0$}
\State trueCount := 0; \Comment{Initial number of paths that satisfy $\psi_k$}
\While{True}
\For{each state $\in$ workingSet that satisfies $\neg \varphi_1 \lor \varphi_2$} \Comment{i.e., path satisfies $\psi_k$}
\State remove state from workingSet; \State trueCount++;
\EndFor
\If{$(N_1(1 - \epsilon_0) \leq$ trueCount)}
\State return $k$; \Comment{trueCount $\geq N_1(1 - \epsilon_0)$, i.e., $\hat{P}(s, \psi_k) = \frac{\text{trueCount}}{N_1} \geq 1 - \epsilon_0$}
\EndIf
\State $k++$;
\State replace current states in workingSet with randomly obtained next states;
\EndWhile
\EndProcedure
\end{algorithmic}
\end{algorithm}

trueCount$/N_1 \geq 1 - \epsilon_0$, the value $k$ is returned. This concludes Phase I of the U2B and initiates the invocation of Phase II.

Remark 2. Algorithm 1 terminates and returns $k$ if and only if $\hat{P}(s, \psi_k) \geq 1 - \epsilon_0$. The above statement holds directly from the facts that $\hat{P}(s, \psi_k)$ is equal to the proportion of paths in sample of size $N_1$ that satisfy $\psi_k$, and that Algorithm 1 considers a workingSet of $N_1$ paths and terminates only when trueCount $\geq N_1(1 - \epsilon_0)$.

5.2 Optimization: Reducing the workingSet in Phase I

Algorithm 1 initializes workingSet to a set (of size $N_1$) of paths of length 0, and maintains a subset of paths that do not satisfy $\psi_k$ until the loop terminating condition at Line 5 is satisfied. This can be expensive in terms of space usage because $N_1$ is often large.

An alternative realization of Phase I has been developed in which only a small subset of the sample (of total size $N_1$) is considered in workingSet. This is achieved from the observation that on termination of Phase I, the number of paths that do not satisfy $\psi_k$ can be at most $N_1 \epsilon_0 - 1$ in the sample of size $N_1$ (as trueCount$/N_1$ is required to be $\geq 1 - \epsilon_0$). Therefore, it is sufficient to consider only $N_1 \epsilon_0$ paths in workingSet at any point in time. Whenever
some paths in workingSet satisfy $\psi_k$, they are replaced with a new set of paths such that the size of workingSet is maintained at $N_1\epsilon_0$. These new paths are extended to length $k$ before $k$ is incremented and the old paths are extended. In short, a sliding window workingSet is considered until the total number of paths that satisfy $\psi_k$ is $\geq N_1(1-\epsilon_0)$ (as required in Phase I). This reduces the space usage as the number of paths stored in workingSet at any time is fixed to $N_1\epsilon_0$, a small proportion of $N_1$.

Figure 5.1 illustrates this strategy. Each sector represents the working set of paths examined at each iteration. The working set size is fixed to $N_1\epsilon_0$. The radius of each sector denotes the length of paths in the corresponding working set. In the figure, initially a working set containing paths of length 1 is considered. The property $\psi_k$ is satisfied in some of these paths and as a result, those paths are removed and new paths of length 1 are generated and added to the working set. All paths in the working set are then extended by one step. This is repeated in iteration 2, at the end of which the working set contains paths of length 3. As per the figure, none of the paths in the working set satisfy $\psi_k$ and as such, no new paths are added to the working set; instead all paths in the working set are extended by one step (i.e., the path
length $k$ becomes 4). The above process is repeated until a sector (working set) is obtained such that (a) it overlaps with the shaded sector and (b) contains a sub-sector of paths (denoted by dotted lines) that satisfy $\psi_k$ and that also overlaps with the shaded sector. This implies that the proportion of paths that satisfy $\psi_k$ is $\geq 1 - \epsilon_0$. Algorithm 2 presents the listing of this optimized implementation.

Algorithm 2 Optimized Implementation of Phase I

1: procedure IDENTIFYK0_OPT_1($N_1, \epsilon_0, \psi$)
   $\triangleright N_1$: Total number of samples for Phase I (see U2B Step 1(a))
   $\triangleright \epsilon_0$: Error bound for Phase I (see U2B Step 1(c))
   $\triangleright \psi := (\varphi_1 \cup \varphi_2) \lor (\neg \varphi_2 \land \neg \varphi_1)$
2:   $k := 0$; $\triangleright$ Initial length of paths
3:   workingSet := add $N_1\epsilon_0$ copies of start state; $\triangleright$ paths of length $k = 0$
4:   trueCount := 0; $\triangleright$ Initial number of paths that satisfy $\psi_k$
5:   while True do
6:     for each state $\in$ workingSet that satisfies $\neg \varphi_1 \lor \varphi_2$ do $\triangleright$ i.e., path satisfies $\psi_k$
7:       remove state from workingSet;
8:     trueCount++;
9:   end for
10:   if ($N_1(1 - \epsilon_0) \leq$ trueCount) then
11:       return $k$; $\triangleright$ trueCount $\geq N_1(1 - \epsilon_0)$, i.e., $\hat{P}(s, \psi_k) = \frac{\text{truecount}}{N_1} \geq 1 - \epsilon_0$
12:   end if
13:   $k++$;
14:   replace current states in workingSet with randomly obtained next states;
15:   run $(N_1\epsilon_0 - |\text{workingSet}|)$ random simulations for $k$ steps from start state;
16:   add last states to workingSet;
17: end while
18: end procedure

The primary differences between Algorithms 1 and 2 are at Lines 3 and 15–16 of Algorithm 2. Instead of initializing workingSet with $N_1$ copies of start states (as in Algorithm 1), it is initialized with $N_1\epsilon_0$ copies of start states. Then, if some states are removed from workingSet (Line 7), it is replenished with the last states of newly extended paths of appropriate length such that the total number of states in workingSet remains equal to $N_1\epsilon_0$ (Line 15, 16).

**Proposition 1.** Algorithm 2 terminates and returns $k$ if and only if $\hat{P}(s, \psi_k) \geq 1 - \epsilon_0$.

Algorithm 2 terminates if $N_1(1 - \epsilon_0) \leq \text{trueCount}$. Therefore, it must examine at least $N_1(1 - \epsilon_0) + 1$ paths before terminating and returning a $k$. That is, at most $N_1\epsilon_0 - 1$ paths are not considered by Algorithm 2 for returning a $k$ and inferring that $\hat{P}(s, \psi_k) \geq 1 - \epsilon_0$. 
The above proposition holds as \( \hat{P}(s, \psi_k) \) is the proportion of paths (i.e., trueCount) in a sample of size \( N_1 \) that satisfy \( \psi_k \) and the terminating condition of Algorithm 2 ensures that trueCount/N₁ ≥ 1 − ϵ₀.

5.2.1 Discussion: Algorithm 1 Vs. Algorithm 2

Recall that Algorithm 1 uses \( N_1 = \frac{1}{2\epsilon_1 \log(\frac{4}{\delta})} \) samples while Algorithm 2 requires \( N_1 \epsilon_0 \) samples. We have considered \( \epsilon_0 = \epsilon_1 = \frac{\epsilon}{3} \) (see Remark 1 in Section 4.3); however any other choice of \( \epsilon_0 \) and \( \epsilon_1 \) as a function of \( \epsilon \) would suffice for this discussion. Figure 5.2 compares the increases (in log scale) in the value of \( N_1 \) and \( N_1 \epsilon_0 \) with the decrease in \( \epsilon \) for a specific confidence parameter \( \delta = 0.001 \). Observe that \( N_1 \) increases faster than \( N_1 \epsilon_0 \) with the decrease in error bound \( \epsilon \) of the U2B method (for instance, with \( \epsilon = 0.001 \), \( N_1 = 1.6 \times 10^7 \) while \( N_1 \epsilon_0 = 5403 \)). In other words, as the precision of the U2B method is increased, Algorithm 2 uses a considerably smaller working set (and in turn, less space) compared to that used by Algorithm 1; the larger the precision, the greater the benefit in terms of space usage in using Algorithm 2 over Algorithm 1.

The space-saving benefit increases with the increase in the number of variables describing the model (i.e., each model state). We have experimented with different variations of a simple queue model (see Jennings et al. (2010)) where each variation contains a different number of variables. Figure 5.3 shows that with the increase in the number of variables in the model, the
Figure 5.3 Memory usage by Algorithm 1 Vs. Algorithm 2 for variations of a simple queue model.

Increase in the space usage (in MB) by Algorithm 1 is larger than that in Algorithm 2. In fact, when the number of variables is $\geq 2500$, Algorithm 1 reports out of memory and terminates without computing any result.
CHAPTER 6 Dealing with Non-termination in U2B

Recall that $F(k)$ is the probability that $\varphi_1 \cup \varphi_2$ is decided in $k$ steps from a state $s$ under consideration. In Section 4.3.1 we introduced the notion of the Decided Graph (D-Graph; Figure 4.1) presenting the valuations of $F(\cdot)$ for different valuations of $k$. In this chapter, we discuss the condition on the valuation of $F(\cdot)$ (and the corresponding shape of the D-Graph) under which the U2B method fails to terminate and propose a heuristic-based alternate method to ensure termination.

Our argument for the applicability of the U2B method requires that as $k \to \infty$, the limit of $F(k) = P(s, \psi_k) \geq 1 - \epsilon_0$ (see Equation 4.5). That is,

$$\lim_{k \to \infty} P(s, \psi_k) \geq 1 - \epsilon_0 \quad (6.1)$$

When the limit is 1, Equation 6.1 is satisfied for any $\epsilon_0$ and hence our method is valid for any $\epsilon_0 \geq 0$. (See Figure 4.1, which illustrates the case when the limit is 1.)

When the limit is not equal to 1, our method works (i.e., Phase I computation terminates) for any $\epsilon_0$ that satisfies the inequality in Equation 6.1. See Figure 6.1 for an example D-Graph from such a model. There are several local plateaus, followed by an unbounded plateau. Note that the requirement of satisfying this inequality does not restrict the applicability of our technique to any specific class of properties or models; our technique can be applied for any until property and for any model as long as the above requirement is satisfied. It is worth mentioning that PRISM’s statistical method is equivalent to choosing $\epsilon_0 = 0$ in our method and hence will fail to provide a result whenever this limit is not equal to 1. In other words, whenever PRISM’s statistical verification method is successful in computing a result, our method also terminates with a result; and furthermore, our method is able to estimate probabilities for many cases where PRISM’s statistical method fails (see discussion in Section 9).
The implication of the limit not being equal to 1 is that $P(s, \neg(tt \lor (\varphi_2 \lor \neg\varphi_1))) > 0$, which happens if and only if there exists a path to a strongly connected component in the model where every state satisfies $(\varphi_1 \land \neg\varphi_2)$. If the probability of such a path (or paths) is greater than $\epsilon_0$ then the Phase I computation will fail to terminate. It is worth mentioning that in such a case, any statistical verification method that does not analyze model transition structure may not be able to compute any result. However, this feature of not analyzing the model allows the application of statistical verification methods (including ours) for the purpose of estimating the probability of properties in systems for which pre-analysis of system-model is not possible due to prohibitively large state-space; or for systems for which only sample simulations of the system can be generated (as needed).

Consider the DTMC model in Figure 6.2. The start state of the model is $s_0$ and each state is annotated with the property $(\varphi_1, \varphi_2)$ that holds at that state. As in the illustrative example introduced in Section 1.1, the dotted segment, denoted by DS, represents some complicated transition structure on $n$ different states (an exact description of the model is available at Jennings et al. (2010)). All states in DS satisfy $\varphi_1$. The objective is to compute $P(s_0, \varphi_1 \lor \varphi_2)$. There are three paths $s_0, s_3, s_3, \ldots, s_0, s_4, s_4, \ldots$ and $s_0, t_0, \ldots, t_m, s_4, \ldots$ that satisfy $\varphi_1 \lor \varphi_2$; therefore, $P(s, \varphi_1 \lor \varphi_2) = 0.2 + 0.2 + 0.4 \times 0.65 = 0.66$. Observe that there exists an infinite path in the model with positive probability where every state satisfies $(\varphi_1 \land \neg\varphi_2)$. In fact, $\lim_{k \to \infty} P(s_0, \psi_k) = 0.86$. As PRISM’s statistical method requires the above limit to be 1, it
fails to compute the estimate of $P(s_0, \varphi_1 U \varphi_2)$. Similarly, our proposed method U2B will fail to terminate when $\epsilon_0 < 0.14$. More precisely, *Phase I* of the U2B method will fail to terminate. In the following, we present a strategy and a corresponding heuristic to address this problem of non-termination.

### 6.1 Rationale

From the semantics of PCTL (Section 2.2), the probability of satisfying $\varphi_1 U \varphi_2$ can be expressed in terms of satisfying $\varphi_1 U^k \varphi_2$ as follows:

$$
\lim_{k \to \infty} P(s, \varphi_1 U^k \varphi_2) = P(s, \varphi_1 U \varphi_2), \text{ i.e., } P(s, \varphi_1 U^\infty \varphi_2) = P(s, \varphi_1 U \varphi_2) \quad (6.2)
$$

Next, suppose there exists a method by which a $k^*$ can be computed such that

$$
\forall \Delta_k \geq 1 : \hat{P}(s, \varphi_1 U^{k^*} \varphi_2) = \hat{P}(s, \varphi_1 U^{k^*+\Delta_k} \varphi_2) \quad (6.3)
$$

We refer to any $k^*$ that satisfies the above equation as an *unbounded-plateau-detector* (the valuation of estimate $\hat{P}(s, \varphi_1 U^{k^*} \varphi_2)$ remains unchanged for all $k \geq k^*$). Note that there is at most one unbounded plateau and an infinite number of unbounded-plateau-detectors. The above equation implies that $\hat{P}(s, \varphi_1 U^{k^*} \varphi_2) = \hat{P}(s, \varphi_1 U^\infty \varphi_2)$. Proceeding further, we prove the following theorem which forms the basis of our method.

**Theorem 2.** Given any precision parameter $\epsilon_1 > 0$ and confidence parameter $\delta_1 > 0$,

$$
Pr \left( \left| \hat{P}(s, \varphi_1 U^{k^*} \varphi_2) - P(s, \varphi_1 U \varphi_2) \right| > \epsilon_1 \right) \leq \delta_1
$$
where $k_*$ is an unbounded-plateau-detector and $\delta_1 \geq 2e^{-2N_1(\epsilon_1)^2}$.

Proof.

\[
|\hat{P}(s, \varphi_1 u^{\leq k_*} \varphi_2) - P(s, \varphi_1 u \varphi_2)| \leq |\hat{P}(s, \varphi_1 u^{\leq k_*} \varphi_2) - \hat{P}(s, \varphi_1 u^{\leq k_*} \varphi_2)|
+ |\hat{P}(s, \varphi_1 u^{\leq k_*} \varphi_2) - P(s, \varphi_1 u^{\leq k_*} \varphi_2)|
\leq |\hat{P}(s, \varphi_1 u^{\leq k_*} \varphi_2) - P(s, \varphi_1 u^{\leq k_*} \varphi_2)|
\]

using Equation 6.2

Therefore,

\[
|\hat{P}(s, \varphi_1 u^{\leq k_*} \varphi_2) - P(s, \varphi_1 u \varphi_2)| \leq |\hat{P}(s, \varphi_1 u^{\leq k_*} \varphi_2) - \hat{P}(s, \varphi_1 u^{\leq k_*} \varphi_2)|
+ |\hat{P}(s, \varphi_1 u^{\leq k_*} \varphi_2) - P(s, \varphi_1 u^{\leq k_*} \varphi_2)|
\leq |\hat{P}(s, \varphi_1 u^{\leq k_*} \varphi_2) - \hat{P}(s, \varphi_1 u^{\leq k_*} \varphi_2)|
+ |\hat{P}(s, \varphi_1 u^{\leq k_*} \varphi_2) - P(s, \varphi_1 u^{\leq k_*} \varphi_2)|
\]

using Equation 6.3

From Lemma 1, the following holds for any $k$, $N_1 \geq 1$ and $\epsilon_1 > 0$

\[
Pr\left(\sup_{k \geq 1} |\hat{P}(s, \varphi_1 u^{\leq k} \varphi_2) - P(s, \varphi_1 u^{\leq k} \varphi_2)| > \epsilon_1\right) \leq 2e^{-2N_1(\epsilon_1)^2}
\]

where $\hat{P}(s, \varphi_1 u^{\leq k} \varphi_2)$ is the proportion of paths (starting from $s$) in $N_1$ samples that satisfy $\varphi_1 u^{\leq k} \varphi_2$. Therefore, from Equation 6.4

\[
Pr\left(|\hat{P}(s, \varphi_1 u^{\leq k} \varphi_2) - P(s, \varphi_1 u^{\leq k} \varphi_2)| > \epsilon_1\right) \leq \delta_1, \text{ i.e.,}
\]

\[
Pr\left(|\hat{P}(s, \varphi_1 u^{\leq k_*} \varphi_2) - P(s, \varphi_1 u \varphi_2)| > \epsilon_1\right) \leq \delta_1
\]

where $\delta_1 \geq 2e^{-2N_1(\epsilon_1)^2}$.

It follows that if $N_1 \geq \frac{1}{2\epsilon_1^2} \log(\frac{\delta_1}{2})$ samples are considered to compute a $k_*$ such that Equation 6.3 is satisfied, then the proportion of paths that satisfy $\varphi_1 u^{\leq k_*} \varphi_2$ in $N_1$ samples (i.e., $\hat{P}(s, \varphi_1 u^{\leq k_*} \varphi_2)$) estimates $P(s, \varphi_1 u \varphi_2)$ with precision parameter $\epsilon_1$ and confidence parameter $\delta_1$.

\[\square\]

The above theorem provides a sound roadmap to estimate $P(s, \varphi_1 u \varphi_2)$ and it does not require that $\lim_{k \to \infty} P(s, \psi_k) \geq 1 - \epsilon_0$ (as is necessary for the termination of Phase I of
our U2B method). However, this roadmap suffers from the drawback that it assumes the existence of a method for computing \( k_* \), an unbounded-plateau-detector. No such method for computing \( k_* \) can be realized in practice. As such, we propose a heuristic for estimating \( k_* \) which ensures termination of U2B at the cost of precision (i.e., the resulting \( \hat{F}(s, \varphi_1 \cup \varphi_2) \) may not be an estimate within pre-specified error bound and confidence parameter) when \( \lim_{k \to \infty} P(s, \psi_k) \not\geq 1 - \epsilon_0 \).

### 6.2 U2B-P: Heuristic for Computing Plateau-Detector using the D-Graph

If in a D-Graph the valuation of \( F(k) = P(s, \psi_k) \) for a range of values of \( k \) (see Figure 6.1) remains unaltered, then a plateau in the corresponding valuation of \( P(s, \varphi_1 \cup \varphi_2) \) occurs for the same \( k \) values. Recall that Phase I of U2B does not terminate when there exists an unbounded plateau in \( F(\cdot) \) such that the value of the plateau is less than \( 1 - \epsilon_0 \). For instance \( F(\cdot) \) for the model in Figure 6.2 has an unbounded plateau with valuation 0.86.

The basis of the heuristic, therefore, is as follows. An estimate \( \hat{k}_a \) of \( k_a \) is said to be “good” if a “long” plateau in \( \hat{F}_{N_1}(k) = \hat{P}(s, \psi_k) \) (estimate of \( F(k) \) from \( N_1 \) samples) is detected starting from \( k = \hat{k}_a \). In other words, given \( \Gamma \), a pre-specified length of a plateau, \( \hat{k}_a \) is an estimate of \( k_a \) if \( \forall k : \hat{k}_a \leq k \leq \hat{k}_a + \Gamma \), the valuation of \( \hat{F}_{N_1}(k) \) remains unaltered.

\[
\forall k : \hat{k}_a \leq k < (\hat{k}_a + \Gamma) : \hat{F}_{N_1}(k) = \hat{F}_{N_1}(k + 1) \Rightarrow \hat{P}(s, \varphi_1 \cup \varphi_2) = \hat{P}(s, \varphi_1 \cup \varphi_2) \quad (6.5)
\]

The precision of this method of estimation depends on the length, \( \Gamma \), of the detected plateau; a longer plateau (larger \( \Gamma \)) is likely to provide a better estimate \( \hat{k}_a \). For example, in Figure 6.1, if \( \Gamma \) is greater than \( k_2 - k_1, k_3 - k_4, \) and \( k_6 - k_5 \), then \( \hat{k}_a \) will be indeed an unbounded-plateau-detector; otherwise, one of the local plateaus may result in an incorrect \( \hat{k}_a \) computation. In the following, we provide a heuristic to obtain a suitable valuation for \( \Gamma \) based on the valuations of \( k \).

Let \( k_i \) be the current valuation of the simulation length and \( k_j \) be the smallest value of \( k \) for which \( \hat{F}_{N_1}(k_i) = \hat{F}_{N_1}(k_j) \). The objective is decide whether the difference \( k_i - k_j \) is a long enough (\( \geq \Gamma \)) to infer that a global plateau is detected. Assuming that \( F(\cdot) \) increases at a
constant rate given by $F(k_j)/k_j$, we estimate the $k_x$ for which $F(k_x) = 1$

\[
\frac{1 - F(k_j)}{k_x - k_j} = \frac{1}{k_x} \iff k_x - k_j = k_j \left( \frac{1}{F(k_j)} - 1 \right)
\]

We say that $\Gamma = (k_j + AF)\gamma^{\text{simpoly}}$ where

- $AF$ is the additive factor ($= 10$).
- $\gamma = \text{MINMAX} \left( LB, \frac{1}{F_{N_1}(k_j)} - 1, UB \right)$,
- $\text{simpoly}$ is a user-specified parameter (default value is 1),
- $LB = 2$ and $UB = 5$ are the pre-specified lower- and upper-bounds of $\gamma$, and
- $F_{N_1}(\cdot)$ is the estimator of $F(\cdot)$ (see Section 4.3.1)

The value $k_j$ is said to be an estimate $\hat{k}_s$ when $k_i - k_j > \Gamma$ and $\hat{F}_{N_1}(k_i) = \hat{F}_{N_1}(k_j)$. Note that we have arbitrarily set the three parameters $AF$, $UB$ and $LB$. $AF$ is used to ensure that a long enough plateau is considered even when $k_j$ is small (e.g., $k_j = 1$). $LB$ (and $UB$) ensures that the required plateau length grows reasonably by exponents of 2 (or 5) if the slope $\hat{F}_{N_1}(k_j)/k_j$ is too large (or too small). We have allowed users the control the length of the plateau using the exponent $\text{simpoly}$.

Consider an example illustration in Figure 6.1. At $k_1$, the value of $\Gamma$ is $k_4 - k_1$ (assume that there is no pre-set $LB$, $UB$, $AF$), i.e., if the value of $\hat{F}_{N_1}(\cdot)$ remains unaltered between $k_1$ and $k_4$ (inclusive), we say that a plateau is identified starting from $k_1$ and the corresponding value of $\hat{P}(s, \varphi_1 \cup \leq k_1 \varphi_2)$ is identified as the $\hat{P}(s, \varphi_1 \cup \varphi_2)$ (see Equation 6.5). Similarly at $k_3$, $\Gamma$ computed using the above formula is $k_7 - k_3$.

We have developed a method, referred to as $U2B_P$, based on the above heuristic to compute $k_j = \hat{k}_s$. In $U2B_P$, if a plateau in $\hat{F}_{N_1}(\cdot)$ is detected starting from $k_j$ and if $\hat{F}_{N_1}(k_j) \neq 1 - \epsilon_0$, then $\hat{P}(s, \varphi_1 \cup \leq k_j \varphi_2)$ is returned as the estimate of $P(s, \varphi_1 \cup \varphi_2)$ (see Theorem 2). $\hat{P}(s, \varphi_1 \cup \leq k_j \varphi_2)$ is the proportion of paths in $N_1$ samples that satisfy $\varphi_1 \cup \leq k_j \varphi_2$. On the other hand, if $\hat{F}_{N_1}(k_j) > 1 - \epsilon_0$, then $U2B_P$ is said to have successfully estimated $k_0$ ($= k_j$) and therefore $U2B_P$ reduces to $U2B$ and invokes Phase II computation (as described in $U2B$ method; see Section 4.3.2).
Algorithm 3: Implementation of U2B_P

1: procedure plateauKStar($N_1, \epsilon_0, \psi, \text{simpoly}$)
   $\triangleright N_1$: Total number of samples for phase 1 (see U2B Step 1(a))
   $\triangleright \epsilon_0$: Error bound for phase 1 (see U2B Step 1(c))
   $\triangleright \psi := (\varphi_1 \cup \varphi_2) \vee (\neg \varphi_2 \cup \neg \varphi_1 \land \neg \varphi_2)$
   $\triangleright \text{simpoly}$: Exponent for plateau length calculation

2: $k := 0$; $\triangleright$ Initial length of paths
3: lastk := 0; $\triangleright$ last value of $k$ for which $\psi_k$ was satisfied
4: workingSet := add $N_1$ copies of start state; $\triangleright$ Initial number of paths that satisfy $\psi_k$
5: trueCount := 0; $\triangleright$ Initial number of paths that satisfy $\varphi_1 \cup \leq k \varphi_2$
6: satCount := 0; $\triangleright$ Initial number of paths that satisfy $\varphi_1 \cup \varphi_2$

7: while (1) do
8:   for each state $\in$ workingSet that satisfies $\neg \varphi_1 \lor \varphi_2$ do $\triangleright$ i.e., path satisfies $\psi_k$
9:     remove state from workingSet;
10:    trueCount++;
11:   if (the state satisfies $\varphi_2$) then
12:     satCount++; $\triangleright$ update satCount
13:   end if
14:   lastk := $k$; $\triangleright$ record value of $k$
15: end for
16: if ($N_1(1 - \epsilon_0) \leq \text{trueCount}$) then
17:   return $k$; $\triangleright$ trueCount $\geq N_1(1 - \epsilon_0)$, i.e., $\hat{P}(s,\psi_k) = \frac{\text{trueCount}}{N_1} \geq 1 - \epsilon_0$
18: end if
19: $k := k++$;
20: replace current states in workingSet with randomly obtained next states;
21: if (trueCount > 0) then
22:   $\Gamma := (\text{lastk} + 10) \times \text{MINMAX}(2, N_1/\text{trueCount} - 1, 5)\text{simpoly};$ $\triangleright$ Calculation of plateau length
23: end if
24: if ($\Gamma > 0$) && ($k > \text{lastk} + \Gamma$) then $\triangleright$ Condition for plateau: heuristic
25:   return $k$ and $\text{satCount}/N_1$ as $\hat{P}(s, \varphi_1 \cup \varphi_2)$
26: end if
27: end while
28: end procedure

Remark 3. As U2B_P is based on a heuristic, it cannot provide any correctness guarantees. We give users the option to deploy either U2B (with the Algorithm 2 implementation for Phase I) or U2B_P. In the event that U2B fails to return an estimated probability within the amount of time the user is willing to wait, the user can terminate the process and deploy U2B_P. We have not deployed U2B_P in any of the experimental results presented in Chapter 8.

The U2B_P method is realized as follows in Algorithm 3. In addition to keeping track of the proportion of paths that satisfy $\psi_k$ (trueCount, i.e., $\hat{F}_{N_1}(k)$), the algorithm also keeps information regarding the number of paths that satisfy $\varphi_1 \cup \leq k \varphi_2$ (satCount in Lines 6, 12).
Figure 6.3 Execution of Algorithm 3 for DTMC model in Figure 6.2: 
trueCount and satCount vs. k.

The value of $k$ for which there is some change in the valuation of trueCount is recorded in lastk (Line 14). $\Gamma$ is computed at Line 22 following the above description. If trueCount does not change for a large range of values of $k$ (i.e., the difference between current value of $k$ and lastk is $> \Gamma$), then for the same range the value of satCount will also not change (Equation 6.5). If a plateau is detected in the value of trueCount (i.e., $F_{N_1} (\cdot)$), then satCount/$N_1$ is returned as an estimate for $P(s, \varphi_1 U \varphi_2)$ along with a warning to the user that a heuristic has been used to satisfy Equation 6.3 (Line 25). The computation can be re-done with larger values of $\Gamma$, if the user so chooses, by increasing simpoly. If the termination condition of the while-loop at Line 8 is satisfied, then it implies that $\hat{F}_{N_1}(k)$ is $\epsilon_0$ close to 1. In that case, the algorithm returns $k$ as $k_0$ (Line 17) and Phase II of U2B is invoked.
6.2.1 Discussion: U2B vs U2B_P

Consider the example model in Figure 6.2. The U2B method will fail to terminate and estimate \( P(s, \varphi_1 U \varphi_2) \) for this model because the limit\(^1 \lim_{k \to \infty} P(s, \psi_k) = 0.86 < 1 - \epsilon_0 \) where \( \epsilon_0 = 0.0025 \). That is, \( P(s, \psi_k) \) or \( F(k) \) has an unbounded plateau for some value of \( k \) and the valuation of \( P(s, \psi_k) \) at the plateau is \( < 1 - \epsilon_0 \).

The U2B_P method as implemented in Algorithm 3, on the other hand, terminates and successfully estimates \( P(s_0, \varphi_1 U \varphi_2) \). In the example, we have considered \( m = 20 \) (number of \( t_i \)-states in the model) and used \( \text{simpoly} = 1 \). Algorithm 3 identifies two plateaus—one where the simulation paths end up in the states \( t_0, \ldots, t_m \) (local plateau) and the other where the simulation paths end up in the \( \text{DS} \) (global plateau). Figure 6.3 shows these plateaus in terms of the changes in the valuation of the \textbf{trueCount} \( \) (number of paths with decided result), \textbf{satCount} \( \) (number of paths that satisfy \( \varphi_1 U \varphi_2 \)).

The execution starts with \( k = 0 \) and \( |\text{workingSet}| = N_1 = 19,171 \) (\( N_1 = 19,171 \) for \( \epsilon_0 = 0.0025 \) and \( \delta = 0.01 \)). The value of \textbf{trueCount} remains at 11,492 until the value of \( k \) becomes 20, i.e., \( \forall k \in [1, 20] : \hat{F}_{N_1}(k) = \hat{P}(s, \psi_k) = 0.59942 \). This is because the length of paths considered is \( \leq 20 \) and as such the transitions \( t_m \) to \( s_4 \) and \( t_m \) to \( s_1 \) are yet to be explored. However, the length (20) of this plateau in \( \hat{F}_{N_1}(\cdot) \) is not considered to be sufficient as per the heuristic because \( \forall \text{lastk} \in [1, 19] : \text{lastk} + \Gamma \geq 23 \) (see the computation of \( \Gamma \) described in Section 6.2). That is, if \( \hat{F}_{N_1}(\cdot) \) remained unaltered for paths of length 23, then U2B_P would infer that a reasonably large size plateau have been detected and, therefore, would terminate. In the current example, that does not happen as \( \hat{F}_{N_1}(20) < \hat{F}_{N_1}(21)^2 \).

The value of \textbf{trueCount} remains at 16,566 for \( k \geq 21 \), i.e., the last time \textbf{trueCount} value changes is when \( k = 21 \). In this case, when \( \text{lastk} = 21 \), \( \Gamma = 62 \). In other words, if the \textbf{trueCount} value does not change for \( k \) between 21 and 21 + 62 = 83, the U2B_P terminates. Observe that changes in \textbf{satCount} follow a similar pattern as \textbf{trueCount}; a

---

\(^1\)Recall that \( \psi_k \) denotes the property stating that \( \varphi_1 U \varphi_2 \) is decided in \( k \) steps. The \( \lim_{k \to \infty} P(s, \psi_k) \geq 1 - \epsilon_0 \) (see Equation 6.1) is required for the termination of Algorithm 2.

\(^2\)If \( m \) is increased to \( > 23 \) and \( \text{simpoly} \) is set to 1, then the heuristic based method U2B_P would terminate, incorrectly infer a plateau, and estimate \( P(s_0, \varphi_1 U \varphi_2) \) incorrectly. That is why U2B_P produces a warning message on termination and recommends that the user re-run U2B_P using different values of \( \text{simpoly} \).
plateau in the valuation of trueCount (i.e., $\hat{F}_{N_1}(k)$) implies a plateau in the valuation of satCount (i.e., $\hat{P}(s_0, \varphi_1 U^{k} \varphi_2)$). As such, on termination $U2B.P$ returns $\hat{P}(s_0, \varphi_1 U^{k} \varphi_2) = \text{satCount}/N_1 = 0.66665$ as the estimate for $P(s_0, \varphi_1 U \varphi_2)$; recall that $P(s, \varphi_1 U \varphi_2) = 0.66$. 
CHAPTER 7 Application to Continuous Time Markov Chain Models

So far, we have shown the application of U2B in the context of probabilistic model checking of unbounded until properties against DTMC models. In this chapter, we discuss its applicability in verifying similar properties for CTMC models. Unlike a DTMC model where transition from one state to another captures the probability of a discrete time step, a Continuous Time Markov Chain (CTMC) model describes the probability with which a system evolves from one state (configuration) to another within $t$ time units. Formally, a CTMC is defined as:

Definition 2. A Continuous Time Markov Chain $\text{CTMC} = (S, s_I, R, L)$, where $S$ is a finite set of states, $s_I \in S$ is the initial or start state, $R : S \times S \rightarrow \mathbb{R}_{\geq 0}$ is the rate matrix, and $L : S \rightarrow \mathcal{P}(AP)$ is the labeling function which labels each state with a set of atomic propositions $\subseteq AP$ that holds in that state.

The rate matrix $R$ in the above definition denotes the rate at which the system evolves from one state to another, while for any $s \in S$, $E(s) = \Sigma_{s' \in S} R(s, s')$ denotes the rate at which the system moves out of the state $s$. This is used as the parameter to the exponential distribution capturing the probability $1 - e^{-E(s) \cdot t}$ of taking an outgoing transition from $s$ within $t$ time units. If $R(s, s') > 0$ for multiple $s'$, then there exists a race between the moves from $s$ to its multiple next states. The probability $T(s, s')$ with which a state $s$ in $\text{CTMC}$ moves to a state $s'$ in single step is equal to the probability that the delay of moving from $s$ to $s'$ is less than those for any other moves from $s$; $T(s, s') = R(s, s')/E(s)$. Based on this observation, a CTMC contains an embedded DTMC which captures the probability of each transition independent of the time at which it occurs.

Definition 3. Baier et al. (2003) Given a $\text{CTMC} = (S, s_I, R, L)$, the corresponding embedded
\[ DTMC, \ emb(DTMC) = (S, s_I, T, L), \] where \( T : S \times S \to [0, 1] \) such that

\[
T(s, s') = \begin{cases} 
R(s, s')/E(s) & \text{if } E(s) > 0 \\
1 & \text{if } E(s) = 0 \text{ and } s' = s \\
0 & \text{if } E(s) = 0 \text{ and } s' \neq s 
\end{cases}
\]

**Paths and Probability Measures.** A path \( \sigma \) in CTMC is a finite or infinite sequence of tuples \((s_0 t_0, s_1 t_1, s_2 t_2, \ldots)\) where \( t_i \) denotes the amount of time the system remains in state \( s_i \). As in DTMC, the set of all infinite paths starting from state \( s \) is denoted by \( \text{Path}_{\text{CTMC}}(s) \). Let \( \sigma[i] \) denote the \( i \)-th state in the path, \( \sigma^i \) denote the suffix of \( \sigma \) starting from \( \sigma[i] \) and \( \sigma@t \) denote the state at time \( t \). Then, \( \sigma@t = \sigma[i] \) where \( i = \text{MIN}(k \mid t \leq \sum_{j=0}^{k} t_j) \). We will use \( \sigma_{\text{emb(DTMC)}} \) to denote \((s_0, s_1, s_2, \ldots)\) which represents a path corresponding to \( \sigma \) in the \( \text{emb(DTMC)} \). Observe that \( \sigma[i] = \sigma_{\text{emb(DTMC)}}[i] \) for \( i \geq 0 \).

\( C(s_0 I_0, s_1 I_1, \ldots, s_{n-1} I_{n-1}, s_n) \) denotes the cylinder set consisting of all paths of the form \( \sigma = (s_0 t_0, s_1 t_1, \ldots) \in \text{Path}_{\text{CTMC}}(s_0) \) such that \( \sigma[i] = s_i \) and \( t_i \in I_i \) for \( i < n \) and \( I \in \mathbb{R}_{\geq 0} \). Proceeding further, \( \text{Pr}_{\text{CTMC}}(C(s_0 I_0, s_1 I_1, \ldots, s_n)) \) is recursively defined as follows.

\[
\text{Pr}_{\text{CTMC}}(C(s_0 I_0, s_1 I_1, \ldots, s_n)) = \begin{cases} 
1 & \text{if } n = 0 \\
\text{Pr}_{\text{CTMC}}(C(s_0 I_0, s_1 I_1, \ldots, s_{n-1})) T(s_{n-1}, s_n) \int_{I_{n-1}} E(s_{n-1}) e^{-E(s_{n-1}) t} dt & \text{otherwise} 
\end{cases} \ (7.1)
\]

Observe that \( T(s_{n-1}, s_n) \) in the above equation corresponds to probability of moving from \( s_{n-1} \) to \( s_n \) in the \( \text{emb(DTMC)} \) (Definition 3). The last term in the above equation captures the probability of exiting \( s_{n-1} \) in the interval \( I_{n-1} \).

**CTMC properties.** Properties of interest for CTMC include transient and steady state properties which are expressed in Continuous Stochastic Logic (CSL), developed by Aziz et al. (1996). Here, we focus on verification of a specific type of CSL property: the time unbounded until property of the form \( \text{Pr}_{\text{CTMC}}(s_1 U^{[0, \infty)} \phi_2) \) which is satisfied by \( s \in S \) such that
\[ P_{\text{CTMC}}(s, \varphi_1 \cup [0, \infty) \varphi_2) \neq r , \text{ where} \]

\[
P_{\text{CTMC}}(s, \varphi_1 \cup [0, \infty) \varphi_2) = P_{\text{CTMC}}(\{ \sigma \in \text{Path}_{\text{CTMC}}(s) : \sigma \models \varphi_1 \cup [0, \infty) \varphi_2 \}) , \quad \text{(7.2)}
\]

\[ \sigma \models \varphi_1 \cup [0, \infty) \varphi_2 \iff \exists a \in [0, \infty) : \sigma @ a \models \varphi_2 \land \forall b < a : \sigma @ b \models \varphi_1 \]

We will use the fact that \( P_{\text{CTMC}}(s, \varphi_1 \cup [0, \infty) \varphi_2) \) is equal to \( P(s, \varphi_1 \cup \varphi_2) \) in the corresponding \( \text{emb}(\text{DTMC}) \). For the completeness of discussion, we present here the proof of the above statement.

\[
P_{\text{CTMC}}(s, \varphi_1 \cup [0, \infty) \varphi_2) = \sum_{\sigma \in \mathcal{Y}} P_{\text{CTMC}}(\sigma)
\]

where \( \mathcal{Y} = \{ \sigma \in \text{Path}_{\text{CTMC}}(s) : \sigma \models \varphi_1 \cup [0, \infty) \varphi_2 \} \)

In the above, consider any path \( \sigma = s_0 t_0, s_1 t_1, \ldots \). From Equation 7.2, \( \exists a \in [0, \infty) : \sigma @ a \models \varphi_2 \)

and \( \forall b < a : \sigma @ b \models \varphi_1 \). Let \( \sigma @ a = \sigma[k] = s_k \). Therefore,

\[ P_{\text{CTMC}}(\sigma^k) = 1 \text{ as } \sigma @ a = \sigma[k] \land \sigma @ a \models \varphi_2 \quad \text{(7.3)} \]

and \( \forall i : 0 \leq i < k \)

\[
P_{\text{CTMC}}(\sigma^i) = \int_0^{\infty} T(s_i, s_{i+1}) E(s_i) e^{-E(s_i) t_i} P_{\text{CTMC}}(\sigma^{i+1}) \, dt_i \quad \text{(7.4)}
\]

From the above,

\[ P_{\text{CTMC}}(\sigma^0) = \int_0^{\infty} T(s_0, s_1) E(s_0) e^{-E(s_0) t_0} P_{\text{CTMC}}(\sigma^1) \, dt_0 = T(s_0, s_1) P_{\text{CTMC}}(\sigma^1) \]

and

\[ P_{\text{CTMC}}(\sigma^1) = \int_0^{\infty} T(s_1, s_2) E(s_1) e^{-E(s_1) t_1} P_{\text{CTMC}}(\sigma^2) \, dt_1 = T(s_1, s_2) P_{\text{CTMC}}(\sigma^2) \]

Proceeding further,

\[ P_{\text{CTMC}}(\sigma) = P_{\text{CTMC}}(\sigma^0) = T(s_0, s_1) T(s_1, s_2) \ldots T(s_{k-1}, s_k) = \prod_{i=0}^{k-1} T(s_i, s_{i+1}) \]
Note that for any $\sigma$ in CTMC there is a corresponding path $\sigma_{emb(DTMC)}$ in the $emb(DTMC)$ such that $\sigma_{emb(DTMC)}[i] = \sigma[i]$ for all $i \geq 0$, and $\sigma \models \varphi_1 \cup [0,\infty) \varphi_2 \Rightarrow \sigma_{emb(DTMC)} \models \varphi_1 \cup \varphi_2$ in the $emb(DTMC)$. Hence,

$$P_{CTMC}(\sigma) = \prod_{i=0}^{k-1} T(s_i, s_{i+1}) = Pr(\sigma_{emb(DTMC)}) \text{ (see Equation 2.1 in Section 2.1)}$$  \hspace{2cm} (7.5)

Furthermore,

$$\sigma \in Path_{CTMC}(s) \Rightarrow \sigma_{emb(DTMC)} \in Path_{emb(DTMC)}(s) \text{ and}$$

$$\pi \in Path_{emb(DTMC)}(s) \Rightarrow \exists \sigma \in Path(s) : \sigma_{emb(DTMC)} = \pi$$  \hspace{2cm} (7.6)

where $Path_{emb(DTMC)}(s)$ denotes the set of paths starting from $s$ in the $emb(DTMC)$. Recall that, $\Upsilon = \{\sigma \in Path_{CTMC}(s) : \sigma \models \varphi_1 \cup [0,\infty) \varphi_2\}$. Let, $\Xi = \{\sigma_{emb(DTMC)} : \sigma \in \Upsilon\}$. From the above, it follows that $\Xi = \{\pi : \pi \in Path_{emb(DTMC)}(s) \land \pi \models \varphi_1 \cup \varphi_2\}$ Therefore, from Equations 7.5 and 7.6

$$P_{CTMC}(s, \varphi_1 \cup [0,\infty) \varphi_2) = \sum_{\sigma \in \Upsilon} Pr_{CTMC}(\sigma) = \sum_{\pi \in \Xi} Pr(\pi)$$

$$= P(s, \varphi_1 \cup \varphi_2) \text{ in the } emb(DTMC) \text{ (see Section 2.1)}$$

Hence, a CSL property of the form $P_{\mathcal{X}}(\varphi_1 \cup [0,\infty) \varphi_2)$ can be verified at any state $s$ in a CTMC by verifying satisfiability of $P_{\mathcal{X}}(\varphi_1 \cup \varphi_2)$ in the corresponding embedded DTMC, $emb(DTMC)$, at the same state $s$. That is, our U2B algorithm is applicable in the verification of $P_{\mathcal{X}}(\varphi_1 \cup [0,\infty) \varphi_2)$ for CTMC models.
We have realized the U2B and U2B_P methods in a tool called PRISM-U2B, which is developed leveraging the existing implementation of the PRISM model checker, as described by Hinton et al. (2006) (available under GNU GPL). The work described here is implemented based on PRISM version 3.3.1. Recently, pre-release versions of PRISM 4 have become available. Implementation in PRISM 4 is discussed in 10.2. Figure 8.1 presents an overview of the various modules used in PRISM-U2B. Observe that PRISM-U2B re-uses PRISM’s user interface, parsers, and simulation engine. Specifically, PRISM-U2B uses PRISM’s input specification language and presents a user interface similar to PRISM. This significantly minimizes the cognitive burden to learn and understand the usage of PRISM-U2B. While simple changes to the PRISM user interface were sufficient to allow for the additional error bounds and confidence parameters used in the two phases of PRISM-U2B, the internal changes to the PRISM simulator are significant. In the following, we discuss the distinguishing aspects of PRISM-U2B with respect to realization of sample path generation.

8.1 Simulator overview

The core of PRISM’s statistical method is the simulation generator engine. It takes as input (a) the model (e.g., DTMC) given in terms of rules and probabilities for transitions as translated from PRISM’s model specification language, and (b) the property (e.g., in PCTL) translated from PRISM’s property specification language. Notably, PRISM does not generate a concrete representation of the model in memory; rather, it reads the model specification as rules that can later be translated into transition probabilities. The simulator then calculates the number of paths (N) required to compute the probability estimate given the user-specified error bound
and confidence parameter. Finally, it iterates $N$ times, in each iteration randomly generating one path up to a pre-specified maximum length $k$ (by default, 10,000) and returns as the probability estimate the proportion among these $N$ paths that satisfy the given property. In the event that the simulator obtains a path in which the given property is not decided (i.e., satisfiability and un-satisfiability cannot be inferred), PRISM fails and requests that the user specify a larger value for $k$.

Note that the methods described here require selecting the next state randomly based on the rules describing the model. This is generally accomplished by generating a uniform random variable and selecting the next state based on the probability distribution from the model. PRISM version 3 uses the `rand` and `srand` functions from the C standard library to generate these values. Younes (2005a) gives more commentary on the application of various random number generators to probabilistic model checking, and recommends the Mersenne twister, developed by Matsumoto and Nishimura (1998). PRISM version 4 uses the Mersenne twister.

The PRISM simulator currently does not support models with multiple initial states; PRISM-U2B inherits this limitation.

8.2 Implementation of PRISM-U2B

As described in Chapter 4, U2B performs model checking in two phases. The changes required to implement U2B are described below. When calls to the simulator are made, the U2B implementation checks for unbounded until properties. If no such properties are found,
Algorithm 4 PRISM’s sample path generation

1: procedure \( (M, s_0, \psi, maxLength) \)
   \( \triangleright M: \) Model transition rules  
   \( \triangleright s_0: \) Initial state  
   \( \triangleright \psi := (\varphi_1 U \varphi_2) \)  
   \( \triangleright maxLength := \) Prespecified maximum path length

2: currentState := \( s_0 \);
3: length := 0;
4: while \( currentState \not\models \psi \land length < maxLength \) do
5: \hspace{1em} \text{for rule } \in M \text{ do}
6: \hspace{2em} \text{if rule matches } currentState \text{ then}
7: \hspace{3em} currentState := \text{next}(\text{rule});
8: \hspace{2em} \text{random selection based on rule}
9: \hspace{2em} length++;  
10: \hspace{1em} \text{break;}
11: \hspace{1em} \text{end if}
12: \hspace{1em} \text{end for}
13: \hspace{1em} \text{end while}
14: \text{if } currentState \models \psi \text{ then return true;}
15: \text{else return false;}
16: \text{end if}
17: \text{end procedure}

the standard PRISM simulator is called. The U2B method can also be bypassed entirely (even for unbounded properties) through a command line switch.

8.2.1 Phase I

PRISM’s path generation method is described by algorithm 4. This method assumes that some rule from the model will match every state. PRISM ensures this condition by adding self-loops to deadlocked states.

Two primary limitations in this procedure make it unsuitable for its direct use in the Phase I of the U2B method in PRISM-U2B. First, the procedure requires the \( maxLength \) parameter, which effectively defines an upper bound on the path length even for unbounded until path properties. Phase I of the U2B method, on the other hand, requires truly unbounded paths in order to calculate an appropriate \( k_0 \). Second, the PRISM simulator operates by creating single paths and extending them until the property under consideration is decided, or until the maximum path length is reached. As U2B does not put any restriction on the path length, the above is not a good strategy for random generation of paths in the Phase I. For instance, for the property \( \varphi_1 U \varphi_2 \), if the path being generated is a part of an unconditional loop in the
model and satisfies the property $\varphi_1 \land \neg \varphi_2$, then the above path generation method will lead to generation of an infinite length path and therefore never terminate. Algorithms proposed in Sections 5 and 6 provide a better strategy for path generation in Phase I of U2B (and U2B_P). This requires that the simulator in PRISM-U2B randomly generate and keep track of multiple paths using the last state in the corresponding path (where the number of states corresponds to the window size in Algorithms 2 and 3 at a time.

Much of the infrastructure required to implement Algorithms 2 and 3 is already present in PRISM. Rather than maintaining a single current state, PRISM-U2B maintains a set of current states and switches between them in order to extend the paths evenly. The maxLength parameter and the length checking condition are simply removed for Phase I.

8.2.2 Phase II

In Phase II, only $k_0$-bounded until properties are considered, where $k_0$ is obtained from Phase I. Therefore, for DTMC models, the PRISM simulator is directly used in Phase II to estimate the $k_0$ bounded until property using $N_2$ (as prescribed by Phase II of U2B) samples of paths with length $k_0$.

8.3 Application to CTMC models

As previously described, the U2B method can be applied to unbounded CSL properties on CTMC models through their embedded DTMCs. Bounded properties in CSL are bounded in time rather than number of steps. One step may represent a relatively small or large amount of time, and steps may vary in the amount of time that they represent. Therefore, there is no direct translation from the step bound calculated by the first phase of the U2B method to a time bound in a CSL property.

When verifying CSL properties on CTMCs, the first phase of PRISM-U2B is essentially identical. Instead of being generated from a probability distribution, paths are generated from the rates on outgoing transitions. Once a step bound $k_0$ has been established, the CSL properties are left unmodified. Instead, the internal maximum path length for the default
PRISM simulator is set to $k_0$. By default, when a path reaches that length, the PRISM simulator prints an error message and does not return a result. For PRISM-U2B, this behavior is modified so that a property is assumed to be false when a path reaches the maximum length.

8.4 Plateau detection

As described in 6.2, there are models and properties for which Algorithm 2 will not terminate. If desired, the user can invoke Algorithm 3 through a command line switch. Algorithm 3 is not deployed by default because it is not known whether the algorithm has found a true plateau without preanalysis of the model.

8.5 PRISM-U2B Usage Description

The interfaces (command line and graphical) of PRISM-U2B follow closely those of PRISM. We proceed by describing various command line options that are added to the existing ones. While in PRISM the statistical model checking can be invoked by

```
prism -sim <model-file> <property-file>
```

the U2B method based statistical model checking can be invoked in PRISM-U2B with an additional qualification of the type of statistical method

```
prism -sim 2 <model-file> <property-file>.
```

PRISM’s statistical method can be invoked by setting sim flag to 1. In the event that all input properties are (step or time) bounded until properties, PRISM-U2B directly invokes PRISM’s existing sampling technique. PRISM’s statistical method allows users to input the error bound, the confidence parameter, and the maximum path lengths. If no such value is specified, PRISM uses the default values of error bound (0.01), confidence parameter ($10^{-10}$) and maximum path length (10,000). In a similar fashion, PRISM-U2B uses default values for the error bounds and the confidence parameters in the two phases of U2B method: $\epsilon_0 = 0.0025$, $\epsilon_1 = 0.0125$, $\epsilon_2 = 0.01$ and $\delta_1 = \delta_2 = 0.005$. PRISM-U2B also allows for user-specified error bounds and confidence parameters for the U2B method. The user can provide specific values for the individual $\epsilon$s
Figure 8.2 PRISM-U2B GUI
(and/or \(\delta s\)) or can provide a single global \(\epsilon\) (and/or a global \(\delta\)). In the latter case, the global error bound is partitioned using the default factors: \(\epsilon_0 = \frac{\epsilon}{10}, \epsilon_1 = \frac{\epsilon}{2}, \epsilon_2 = 2\frac{\epsilon}{5}\), and the global confidence parameter is partitioned into two equal halves for \(\delta_1\) and \(\delta_2\). For instance,

\[
\text{prism -sim 2 -simepsilon 0.002 0.001 0.01 -simdelta 0.0001}
\]

\[
\text{<model-file> <property-file>}
\]

This provides as input \(\epsilon_0 = 0.002, \epsilon_1 = 0.001, \epsilon_2 = 0.01\), and a global \(\delta = 0.0001\). In the above, \text{PRISM-U2B} uses Algorithm 2 for computing \(k_0\) in Phase I. If the user chooses to use method \text{U2B-P}, he or she can invoke

\[
\text{prism -sim 2 -simpoly 3 <model-file> <property-file>}
\]

The value of the switch \text{simplify} controls the length of plateau (as discussed in Section 6.2) and ensures the termination of statistical sampling based method. Inputs can be supplied in a similar fashion when \text{PRISM-U2B} is invoked via the graphical user interface (Figure 8.2). The tool, \text{PRISM-U2B}, along with its source code, sample models, and documentation, is available from Jennings et al. (2010).
CHAPTER 9  Experimental Evaluation

We evaluate the proposed U2B method and its realization in PRISM-U2B using a number of case studies available in the PRISM example suite. The objective of this empirical study is to show the effectiveness of the U2B method with respect to (a) precision of estimate, (b) computation time, and (c) memory usage. We proceed by describing in brief the various case studies in Section 9.1 followed by a detailed analysis of empirical results in Sections 9.2 and 9.3.

9.1 Case Studies

As noted before, PRISM-U2B re-uses PRISM’s input specification language and language parsers, and therefore, our experiments directly use several case studies from the PRISM example suite. PRISM (and by extension PRISM-U2B) allows for a specific type of PCTL and CSL property syntax, which essentially queries the probability with which certain path property is satisfied by the system under consideration. The syntax for such a query is $P=?[\text{path-property}]$. The result of such a query is the probability with which the paths from the start state of the system satisfies path-property. In the following, we will discuss case studies and consider several property queries. The results obtained by applying PRISM’s numerical method (whenever possible) will be used to evaluate and compare the precision of results obtained by applying PRISM’s statistical method and the U2B method of PRISM-U2B.

9.1.1 Randomized Dining Philosopher

This is a DTMC model represented a probabilistic variation of the standard dining philosopher protocol. The model is analyzed against a PCTL until property query to obtain the probability
that the first philosopher is able to eat before any other philosophers. That is,

\[ P=?[ \text{"allhungry" U ("othershungry" & "eat") } ] \]

where \text{allhungry} denotes that none of the philosophers have eaten, \text{othershungry} denotes that all but the first philosopher have not eaten and \text{eat} denotes that the first philosopher is able to eat. Experiments are conducted by varying the number of philosophers in the model. Available at: Jennings et al. (2010).

### 9.1.2 Simple Queue

This is a DTMC model of a queue in which requests are either received or serviced with a particular probability distribution. If too many requests are received before they can be serviced, then there is an overflow of requests. The property considered computes the probability with which the queue eventually reaches such a state.

\[ P=?[ \text{true U "overflow"}] \]

Experiments are conducted by varying the size of the buffer (queue states) in the model. Available at: Jennings et al. (2010).

### 9.1.3 IPv4 Zeroconf Protocol

This is a simplified DTMC model created by Sen et al. (2005) representing the IPv4 Zeroconf Protocol. Similar to the overflow state in the queue model, it has an error state; it is not desirable for the system executing the protocol to be in such a state. The property query used in our experiments is

\[ P=?[ \text{true U "error"}] \]

As in the queue, experiments are conducted by varying the number of states (denoting the number of intermediate nodes in the network) in the Zeroconf protocol.
9.1.4 Crowds Protocol

This is a DTMC model of a protocol from Reiter and Rabin (1998) for anonymous Web browsing. The protocol is intended to minimize the chance that eavesdropping adversaries will be effective in identifying the individual users by spying on network traffic. Experiments are done with models containing 50, 100 and 200 hosts (size of the crowd) and four adversaries. The property query involves estimating the probability that the identity of an user is divulged, which happens when at least two adversaries observe (agree on) the user’s identity.

\[ P=?[true \ U (observe0>1)] \]

In the above, \( \text{observe}[i] \) denotes the number of adversaries that have observed the user \( i \).

Available at: http://www.prismmodelchecker.org/casestudies/crowds.php.

9.1.5 Broadcast Protocol

This is a DTMC model of a simple broadcast protocol based on gossiping, where each node in the network forwards the message it receives to its neighbors with a pre-specified probability. Two variations of the protocol are considered. In the synchronous, no-collision variation, the nodes send and receive messages simultaneously over independent channels (thereby ensuring freedom from collision). The synchronous, lossy variation, on the other hand, assumes that the neighboring nodes share a channel, which may result in collisions and message loss. The property query of interest involves computing the probability with which certain nodes (e.g., nodes 1 and 2) receive the broadcast message.

\[ P=?[ \text{true} \ U (active1=0)] \text{ and } P=?[ \text{true} \ U (active2=0)] \]

In the above \( \text{active}[i] \) is equal to 0 when a node goes to sleep after receiving (and possibly forwarding) message.

Available at: http://www.prismmodelchecker.org/casestudies/prob_broadcast.php.
9.1.6 EGL Contract Signing Protocol

EGL Contract signing protocol describes a method by which two parties can reach an agreement by exchanging their respective secrets. The protocol is said to be *fair* if and only if the exchange of messages following the protocol guarantees that either both participants obtain the other’s secret or none do. A DTMC model of the EGL contract signing protocol is considered. A property query is considered to demonstrate that the protocol is flawed with respect to fairness. That is, the property captures the fact that one participant gets access to the other party’s secret without communicating its own secrets.

\[ P=?[ \text{true U } (!kA \& kB) ] \]

In the above, \(kA\) and \(kB\) denotes the states where participants A and B *have knowledge* of the other’s secret.

9.1.7 Simple Dice Protocol

This is a DTMC model where the possible outcomes of rolling a fair die are captured using multiple flips of a fair coin. The result of the property query against which the model is analyzed is the probability of obtaining a specific roll of the die. For instance,

\[ P=?[ \text{true U } (s=7 \& d=6) ] \]

is a PCTL property querying the probability of obtaining a roll of 6 on a single die.

Available at: [http://www.prismmodelchecker.org/casestudies/dice.php](http://www.prismmodelchecker.org/casestudies/dice.php)

9.1.8 Embedded Control System

This is a CTMC model of an embedded data collection system with built-in redundancy. The controller ensures that the system shuts down if any module in the system is down (due to possible malfunction) for a certain number of cycles (e.g., 20,000). The property queries the probability that the cause of shut down is attributed to a sensor failure. It is represented in PCTL query as follows.
9.1.9 Cyclic Server Polling System

This is a CTMC model of a polling system consisting of multiple workstations that are being served by a single server. The CSL property that is used for our evaluation is

\[ P = \mathbb{P}[ \neg (s=2 & a=1) \cup (s=1 & a=1) ] \]

which queries the probability with which the first workstation in the system is served before the second one. Experiments are conducted by varying the number of workstations in the system.

Available at: http://www.prismmodelchecker.org/casestudies/polling.php

9.2 Precision, Computation Time and Memory Usage

The experimental evaluation is based on the illustrative example discussed in Chapter 1 and the case studies described in Section 9.1. All experiments are conducted on Red Hat Enterprise Linux 5.1 running on Intel Core 2 Duo 3GHz CPU and 2GB memory. The results for PRISM-U2B are obtained by using the Algorithm 2 as all the examples considered from the PRISM example suite satisfy the condition \( \lim_{k \to \infty} P(s, \psi_k) \geq 1 - \epsilon_0 \) as required for the termination of Phase I in the U2B method.

9.2.1 Precision & Computation Time

We show that the estimate obtained using U2B method is as precise as the statistical method provided by the PRISM tool given the error bounds and confidence parameters. Furthermore, the U2B method is as efficient as (and typically about 1.5 times faster than) PRISM's statistical method.

Table 9.1 provides a summary of our results. For each of the methods, the table presents the probability and its estimates, and the computation time. For the statistical methods, the

Table 9.1 Summary of Results: PRISM vs. PRISM-U2B
bounds on the sample path lengths are also reported: \( \bar{k} \) denotes the maximum path length considered by PRISM’s statistical method and \( k_0 \) denotes the maximum path length considered by PRISM-U2B (the bound obtained automatically from Phase I of U2B).

For the illustrative example, PRISM fails to compute any result, while PRISM-U2B successfully terminates with a good estimate. For the randomized dining philosopher example, PRISM’s numerical method fails to compute any result when the number of philosophers is \( \geq 12 \) due to prohibitively large state-space of the DTMC model (details in Section 9.2.2), whereas PRISM’s statistical method and U2B successfully compute the estimate. For the simplified queue model, PRISM’s numerical method and statistical method both require updates to the default value for maximum number of Jacobi iterations or the maximum simulation path length. The U2B method does not require any such user guidance.

Observe that for the rest of the case studies, PRISM-U2B typically outperforms PRISM’s statistical method (timing results shown in bold). While both U2B in Phase II and PRISM’s statistical method use the same sampling technique, the former uses a much smaller sample path length bound (\( k_0 \) obtained via Phase I) compared to PRISM’s statistical method (which uses \( \bar{k} \); see Table 9.1). Recall that the default value for sample path length in PRISM’s statistical method is 10,000 and may require the user to specify a greater value for some examples. The U2B method uses Phase I to compute a model dependent path length bound \( k_0 \). The gain in computation time achieved by using \( k_0 \) in Phase II of U2B instead of the sample path lengths used in PRISM’s statistical method surpasses the loss in computation time spent computing \( k_0 \) in Phase I.

9.2.2 Memory Usage

Another important consideration is the memory consumed by each of the methods. Figure 9.1 is a graph of the memory usage (in terms of KB) for the case studies for each of the methods. As all the methods are realized in the PRISM model checking engine, each incurs a minimal overhead of \( \sim 30\text{MB} \). The memory usage is comparable for all the methods for models that have small state-space. As expected, for models in which the state-space is large (e.g.,
randomized dining philosopher and embedded control system), PRISM’s numerical method uses much more memory than the statistical methods (in PRISM and PRISM-U2B). Figure 9.2 shows the increase in the memory usage by PRISM’s numerical method with the increase in the number of philosophers in the randomized dining philosopher case study. PRISM’s numerical method fails due to the large memory requirement when the number of philosophers is greater than 11. Observe that the statistical methods do not suffer from such an increase in the memory usage with the increase the state-space of the model.

It is worth mentioning that U2B method in general is expected to use more memory than that used by the statistical method of PRISM as U2B method stores $N_1\epsilon_0$ states for the Phase $I$ computation (for $\epsilon_0 = 0.0025$ and $\delta = 0.001$, $N_1\epsilon_0 = 48$).

9.2.3 Summary of results

The results empirically show that the U2B method as implemented in PRISM-U2B is (a) as
time-efficient as PRISM’s statistical method (and in many cases outperforms PRISM’s statistical
method), (b) as precise as PRISM’s statistical method, and (c) successfully computes results
automatically for cases where PRISM fails or requires user guidance (to increase the maximum Jacobi iterations for the numerical method or the maximum sample path length for the numerical method). Finally, as PRISM-U2B utilizes the model specification language, graphical
user interface, and command-line interface of PRISM, it enjoys (as does PRISM) a high rating among all the probabilistic model checkers in terms of usability, as determined by Jansen et al. (2007). In short, PRISM-U2B broadens the scope of application of approximate probabilistic model checking based on statistical methods; it is not only more efficient and effective than one of the most widely used statistical method as implemented in PRISM but also has been proven (theoretically and empirically) to be applicable in case studies where PRISM fails.

9.3 Comparison with the MRMC tool

Katoen and Zapreev have performed extensive comparison of the statistical model checking tools MRMC (based on Zapreev (2008)), VESTA (based on Sen et al. (2005)), and Ymer (based on Younes and Simmons (2002)); and concluded that MRMC is the fastest among the three. The version of Ymer used in this study did not allow verification of (time) unbounded until properties, while VESTA and MRMC do support verification of these properties. Recall from Chapter 3 that the statistical method in VESTA suffers from two main drawbacks which restrict its correct application in models with loops (see Younes and Simmons (2006); He et al. (2010) for details). Furthermore, we were unable to obtain the tool from the authors (personal communication with Koushik Sen dated: 11/04/2010). While the tool MRMC does not have any
such restriction, it requires prior analysis of the model transition structure to correctly verify unbounded until properties even when using the sampling based method. In the following, we compare MRMC and PRISM-U2B, and discuss their distinguishing aspects.

Markov Reward Model Checker supports verification of probabilistic temporal logic properties (PCTL, CSL, etc.) against different types of probabilistic models (DTMC, CTMC, etc.) using both numerical and statistical sampling based methods. MRMC’s statistical method utilizes confidence interval based estimation to control the error in inferring whether the null hypothesis is correctly rejected or not. As this method utilizes both confidence interval based statistical estimation (Section 3.1.3) and hypothesis testing (Section 3.1.1), we present below an overview of the technique to clearly explain the user-specified inputs that are necessary for correct application of MRMC’s statistical method.

Recall that PRISM and PRISM-U2B are meant to compute the probability of satisfying a given path property within pre-specified error margin and with a certain confidence bound. In contrast, probabilistic queries in MRMC are of the form \( P_{\succ r}(\psi) \), where \( \succ \in \{<,>,\leq,\geq\} \) and \( \psi \) is a path property. Therefore, the result or output of MRMC is boolean. More precisely, MRMC uses the statistical estimate \( \hat{p} \) using the confidence interval and infers that the relation \( \hat{p} \succ r \) holds when the confidence interval does not include \( r \). For instance, if \( \succ \) is equal to \( \geq \), then the method can provide a definitive answer (true) when lower bound of the confidence interval is greater than \( r \), and a definitive answer (false) when the upper bound of the confidence interval is less than \( r \). However, due to the probabilistic nature of the confidence interval, it is necessary to assume that \( r \) is at least \( \xi \) distance from the true probability (where the indifference width is 2\( \xi \); see Section 3.1.1) and that the confidence interval is tighter than \( \xi \). In short, MRMC draws from techniques used in hypothesis testing (as applied in probabilistic model checking) as well as confidence interval based statistical estimation. MRMC therefore requires the following user inputs: confidence level \( \delta \) for estimation using the confidence interval and 2\( \xi' \), the confidence interval (such that \( \xi' < \xi \)). That is, \( \xi' \) corresponds to the \( \epsilon \) used in PRISM-U2B.

Zapreev (2008) proposes a technique (realized in the tool MRMC) that deals with unbounded until properties by pre-analyzing the model under consideration. More specifically, for the
property \( \varphi_1 \cup \varphi_2 \), the sampling based method in \textit{MRMC} first identifies (and discards) the states that never lead to any state satisfying \( \varphi_1 \cup \varphi_2 \). Such reachability analysis requires complete knowledge of the model transition structure, which may not be possible when the model state-space is prohibitively large or the model of the system is not available (only samples simulations can be generated as needed).

Another important difference between \textit{MRMC} and both \textit{PRISM} and \textit{PRISM-U2B} (which possibly stems from \textit{MRMC}’s requirement to pre-analyze the model) is that \textit{MRMC} reads/loads the entire transition matrix of the probabilistic model for its sampling based method. Therefore, the memory usage of sampling based method in \textit{MRMC} is similar to that of numerical methods (e.g., in \textit{PRISM}’s numerical method modulo the differences that stem from a different implementation framework). This significantly reduces the applicability of \textit{MRMC}’s sampling based method for large systems. In fact, for several examples in Table 9.1, we cannot obtain results using \textit{MRMC} as it leads to an out-of-memory error.

\textit{MRMC} does not have a modeling language of its own. The input files are simply the full transition matrix. \textit{PRISM} provides the option of exporting \textit{MRMC}-formatted files for use in \textit{MRMC}; the authors suggest using this method for generating models. For several of the models in Table 9.1, \textit{PRISM} is unable to export the files because of the large size of the models.

Table 9.2 summarizes the results of our experiments with \textit{MRMC}. We have used an identical \( \delta = 0.01 \) (confidence parameter) and \( \epsilon = \xi' = 0.025 \) for the experiments. As \textit{MRMC} tests whether the estimate is related to a given value \( r \) using \( \preceq \) relation and requires that the true \( p \) be \( \xi > \xi' \) distance away from \( r \), we have set \( r \) to be equal to \( p + \xi \) where \( \xi = 0.026 > \xi' \). This allows \textit{MRMC} to provide definitive answers (true or false) in all the cases. If \( \xi' \) is chosen to be greater than \( \xi \), \textit{MRMC} fails to compute a definitive answer. Note that no such assumption is required for the validity of our method as implemented in \textit{PRISM-U2B}.

In the table, the column \( p \) corresponds to the “actual” probability of satisfying the property being considered. It is either computed manually, computed by \textit{PRISM}’s numerical method, or estimated by \textit{PRISM}’s statistical method. The query input to \textit{MRMC} tests whether the estimated probability \( \preceq p \pm 0.026 \). The boundaries of the confidence interval estimated by \textit{MRMC} are

Table 9.2 Summary of results: MRMC vs. PRISM-U2B
presented in the columns Lower bound and Upper bound. MRMC produces results faster than PRISM-U2B in all the cases where it is successful in computing the result. This is because (as noted above) MRMC analyzes the model before performing sampling based confidence interval estimation. That is, MRMC does not deploy a pure sampling based statistical method. This is advantageous for smaller models whose reachability can be performed. In fact, in some cases, sampling may not be even necessary. For instance, for the contract signing protocol, MRMC produces a definitive answer (infers that the property is satisfied) without using any samples. However, if such pre-analysis of the model is not possible, then MRMC fails. This happens for several examples when the transition matrix is too large to be exported from PRISM to MRMC (e.g. the example in Figure 1.1, Crowds protocol of size $\geq 100$, Embedded Control System, Cyclic Server Polling System of size 20) or when the reachability analysis fails in MRMC (Dining philosopher protocol with $\geq 10$ philosophers, Crowds protocol of size 50).

In summary, the following aspects distinguish PRISM-U2B from MRMC:

1. MRMC relies on reachability analysis in addition to samples to compute the results. PRISM-U2B deploys a pure sampling based method. For the case studies for which MRMC can perform reachability analysis, MRMC computes verification result faster than PRISM-U2B.

2. MRMC fails for models where the transition matrix is too large for loading or for performing reachability analysis. PRISM-U2B can be used for comparatively larger models.

3. MRMC requires that the user-input $\xi'$ (the parameter specifying the confidence interval size) be smaller than the distance (half of indifference width) of $r$ from the true $p$ in the query of the form $P_{x,r}(\psi)$ where $x$ belongs to $\{<,\leq,>,\geq\}$. There is no such requirement for PRISM-U2B. While MRMC may not be able to compute a definitive answer when the confidence interval size is not less than the indifference width, the U2B algorithm in PRISM-U2B may not always terminate (Chapter 6). None of the case studies, however, led to the non-termination of the U2B algorithm in PRISM-U2B.
CHAPTER 10 Conclusion

10.1 Conclusion

We have presented U2B, an approximate probabilistic model checking method based on statistical sampling. The method does not require any prior information regarding the structure of the model being verified and therefore can be used in a setting where only sample simulations of the model can be generated. The method can be applied for verifying untimed properties in both DTMC and CTMC models. We have proved the correctness of the U2B method and have discussed the optimized realization of the U2B method. We have also explored a class of examples where PRISM’s statistical method will not be able to estimate a result and the U2B method will suffer from non-termination. We have explained the cause of such problems in terms of the notion of a “plateau” in the D-Graph. We have developed U2B_P, a heuristic-based plateau-detection method, to deal with the non-termination problem. Finally, we have incorporated the U2B and U2B_P methods in the PRISM tool to develop PRISM-U2B, and conducted a detailed experimental study using different probabilistic models. The experiments show the effectiveness of the tool PRISM-U2B in terms of precision, computation time and broader applicability (for large probabilistic models).

10.2 Future work

10.2.1 Implementation in PRISM version 4

PRISM version 4 introduces significant changes to the simulator architecture. The new version implements a frontend/backend approach such that different probabilistic methods can be “plugged in” in order to perform model checking. This allows any of the different model
checking methods described in Chapter 3 to be implemented within PRISM. Currently the methods described by Herault et al. (2004) and Younes and Simmons (2002) are implemented.

This new architecture does not directly ease the implementation of U2B, because all of the approaches described in Chapter 3 are implemented by checking one simulation path at a time, not multiple paths as required by U2B. Therefore, U2B will be implemented as a layer above the new PRISM simulator. This format will also allow Phase II to utilize any of the implemented methods, rather than only the approach implemented in PRISM version 3.

The basic U2B method has already been ported to PRISM 4. A more thorough investigation would involve experimental comparison amongst PRISM 3, PRISM 4, PRISM-U2B as a modification to PRISM 3, and PRISM-U2B as a modification to PRISM 4.

10.2.2 Termination of Phase I

The current heuristic for termination of Phase I is unsatisfactory in the sense that it requires the user either to have knowledge of the model (and thus know that when a true plateau will be reached); or guess when a true plateau has been reached. Although some guidance about the length of a plateau is provided by the current implementation, in general the user will not know with certainty when it is appropriate to deploy U2B_P.

As part of future work, we plan to study the feasibility of identifying and pre-computing only the necessary information (regarding the model transition structure) required to guarantee the termination of Phase I of the U2B method. If this computation can be made less complex than numerical model checking, it may be possible to remove the user-specified parameter from U2B_P.

10.2.3 Markov decision processes

We also plan to develop statistical sampling based methods to verify untimed, unbounded path properties of Markov Decision Processes (MDP). An MDP is a probabilistic model which includes both probabilistic and non-deterministic choices in its transition system. The verification objective for an MDP is to compute the maximum or the minimum probability with which
a state satisfies a given path property. Such computation requires identifying a strategy for selecting next states at non-deterministic choice points, where each strategy results in a DTMC embedded in the corresponding MDP.

It is known that for any MDP, there exist memoryless schedulers that correspond to the minimum and maximum probabilities. A naive method would be to apply U2B for every possible memoryless scheduler and then select the optimum. However, the number of memoryless schedulers is $O(|S|^n)$, where $n$ is the maximum number of non-deterministic choices at any state in the model, and $|S|$ is the number of states.

Work is underway on a method that attempts to sample some subset of the memoryless schedulers and bound the probability of selecting a scheduler that is less than optimal. Both the selection of the scheduler and the model checking of the underlying DTMC could be probabilistic, thus avoiding the problem of state space explosion.
