Introduction

A 1989 review of research related to the improvement of nectar production in plants by Shuel²⁶ presents evidence in support of intentional selection of plant genotypes for better nectar production. Such superior genotypes could be of great benefit for both beekeepers and other agricultural producers.

The selection of better nectar-producing plants to improve honey production requires a reliable and efficient system for screening large numbers of candidate plants. Physical measurement of nectar production, using centrifugation²⁶, capillary tubes²⁷, filter-paper wicks¹⁶, or water extraction²⁸, is often feasible; but for plants with large numbers of small flowers, estimates of total nectar production can be very labour intensive and may not accurately measure the amount of nectar available to the honey bees.

The authors have been selecting populations of perennial Labiatae for improved nectar production²⁵,²⁶ and have wanted an efficient method to screen large numbers of variable plant populations. As an alternative to direct measurements of nectar production, one can rank populations on the basis of measurements of honey bee visitation. However, this would be effective only if there were a strong positive correlation between nectar production and bee visitation and if accurate bee counts could be performed more easily than direct nectar measurements.

In preliminary field plots, we found that accurate and repeatable bee counts could be obtained more readily than could sufficient data from direct nectar measurements for Agastache spp. and Pycnanthemum spp. However, the relationship between nectar production and bee visitation remained to be determined. In preparation for experiments to evaluate this relationship in our test populations, we prepared a literature review that serves as the basis for this report. This review examines published reports that evaluate the relationship between nectar production and honey bee preference among different plant populations.

These reports help to answer some questions about the efficiency of honey bees in judging food resources. But there are factors that can vary among plants tested that could interfere with generalizations about bee efficiency. For instance, although one plant may produce more nectar sugar than another, it could have

Bee World 73 (3) 119–127 (1992)
flowers shaped to make a bee's feeding more difficult. In such a case, the efficient bee might still choose the plant with less nectar production.

Relationships between nectar production and bee visitation

Forage legumes have been popular experimental organisms for studies of the relationship between nectar production and bee preference because of their agronomic importance and inconsistent seed production. Such studies, however, are often confounded by variation for factors other than nectar production that influence bee visitation, such as ease of tripping, aroma, corolla tube length, and colour. Keeping these limitations in mind, we identified for analysis ten reports of field studies that examine the relationship between nectar production in forage legumes and honey bee visitation.

Table 1 summarizes the results of these ten reports. Seven reports indicate a positive statistical relationship between nectar sugar production or nectar volume and honey bee visitation, with three of these reporting that more than half the observed variability in bee visitation could be accounted for by differences in nectar sugar production. The remaining three reports do not show any statistical relationship. Two failed to collect data to evaluate the role that differences in floral density can play in bee preference, and one was also confounded by significant differences in floral aroma. One should note, however, that the primary purpose of Loper and Waller's study was to measure the influence of floral aroma on bee preference, not to measure whole-plant nectar production. Differences in floral aroma and in ease of tripping may also have contributed to the lack of a statistical relationship in Jablonski's report.

None of these papers reported a significant negative relationship between nectar sugar production and honey bee preference.

There has been great interest in the role that honey bee preference plays in fruit and seed production for plants other than forage legumes. This interest, however, has rarely been expressed in the form of well-designed scientific investigations of the relationship between nectar production and honey bee visitation.

The following paragraphs consider five reports we identified that scientifically test this relationship for plants other than forage legumes. In addition, we found evidence of three other studies suggesting that honey bee visitation is positively correlated with nectar production of *Helianthus annuus* in Hungary and in the USA, and of *Vaccinium corymbosum* in the USA. These reports contain statements supporting such a correlation, but present no data for objective analysis and will not be considered further.

Table 2 summarizes the results of five studies of plants other than forage legumes. Three of these studies indicate a positive relationship between nectar production and honey bee visitation. The report by Ayers *et al.* is especially interesting for it is the only study that evaluates selected populations of plants grown exclusively for bees, including *Agastache rugosa, Asclepias tuberosa, Echinops sphaerocephalus, Leonurus cardiaca, Nepeta cataria, Scrophularia nodosa,* and *Trifolium pratense*. The authors examined plants with great variation in nectar production.

</table>
The strength of the correlation in their study is particularly high (table 2), suggesting that weaker correlation coefficients in other studies may be associated with less variability in nectar production among plants evaluated. This was clearly evident in Eriksson's study of *Trifolium pratense*, in which nectar production varied little among the eight cultivars examined.

Although there were large differences in nectar volume and sugar concentration in nine Labiatae (*Coridothymus capitatus*, *Melissa officinalis*, *Phlomis viscosa*, *Rosmarinus officinalis*, *Salvia fruticosa*, *Salvia hierosolymitana*, *Salvia judaica*, *Satureja thymbra*, and *Stachys aegyptiaca*) evaluated by Dafni et al., these differences were not well correlated with bee preference. This may have resulted because the study did not measure the quantity of nectar actually available to honey bees. Four plant species had corolla tubes at least 9 mm long, and these plants were rarely visited by honey bees. Of the five species with shorter corolla tubes, three (*C. capitatus*, *R. officinalis*, and *Stachys aegyptiaca*) showed highly significant correlations between the number of open flowers and honey bee visitation. The authors did not report on the relationship between the number of open flowers and total nectar sugar production, but their data suggest that this would be a worthwhile area for investigation. If one assumes that the nectar volume and sugar concentration of individual flowers of these three species do not vary significantly with flower number, there appears to be a linear relationship between total nectar-sugar production and honey bee visitation.

The only study of plants other than forage legumes that showed no relationship between nectar sugar and bee visitation is that by Mayer et al. for *Malus* spp. The cultivars studied had

white, pink, red, or rose flowers, and visible flower colour and UV reflectance over- rode any possible effect of nectar production on bee behaviour. This study supports Mayer’s earlier observation³⁰ that honey bees foraging on white apple blossoms avoid pink and red flowers, which is probably because of the wavelengths of light that bees perceive⁴.

Conclusion

Published reports of fifteen field studies investigating possible relationships between nectar production and honey bee visitation were analysed. Ten studies showed a positive relationship between nectar volume or nectar sugar production and bee visitation. Of the remaining five studies, three did not consider the influence of floral density on bee preference⁹-²⁰. Variation in floral aroma complicated results in studies of Medicago by Loper and Waller²² and of Helianthus by Fonta et al.²⁶. Differences in flower colour were important confounding factors in Malus²⁴ and Medicago⁶. And differences in floral morphology strongly influenced the results of Dafni et al.³ for Labiatae.

Researchers wishing to use bee count data to infer differences in nectar production must answer the following questions:

1. Do the plants to be evaluated vary widely in nectar production? If they do not, any differences observed in bee preference will likely be due to factors other than nectar production. These factors may be less important in no-choice situations than they are in choice tests.

2. Do the plants differ in availability of nectar to honey bees? Although plants with long corolla tubes may produce large quantities of nectar, other insect visitors may exclude honey bees from these plants.

3. Do some of these plants emit undesirable aromas or display flower colours that bees cannot perceive? Such variation can confound results.

4. Are bees using these plants primarily for nectar, or is pollen collection important? If pollen collection is important, bee preference may be more closely related to pollen production than to nectar production.

If these questions can be satisfactorily answered, researchers may be justified in using bee count data as an alternative to direct measurements of nectar production to rank plant populations. Whether or not there is a strict relationship between nectar production and bee visitation, bee count data are an essential part of any programme to select superior bee forage.
