Abstract
A privately-owned southern tamandua (Tamandua tetradactyla) and a capybara (Hydrochoeris hydrochaeris) were presented for severe pruritus. Superficial skin scrapings revealed numerous Sarcoptes scabiei mites. Morphological examination and mitochondrial DNA sequencing revealed that both patients were infested with Sarcoptes scabiei. The animals were treated with selamectin (9 mg/kg) topically once, and the owner was instructed to repeat treatment in two weeks. The tamandua died of unknown causes three weeks after initial examination before reevaluation could occur. Clinical signs and skin lesions in the capybara resolved after two treatments with selamectin. This is the first documented report of sarcoptic mange in a southern tamandua. In addition, this is the first documented case of natural transmission of Sarcoptes mites between a tamandua and capybara in captivity. Finally, this is the first described use of topical selamectin for the treatment and resolution of sarcoptic mange in a capybara.

Naturally Acquired *Sarcoptes scabiei* Infestation in a Captive Southern Tamandua (*Tamandua tetradactyla*) and a Capybara (*Hydrochoeris hydrochaeris*)

**Case Report**

*Sarcoptes scabiei* was first a human parasite that spread to various domestic and captive animal hosts, and later moved to certain wildlife species, especially canids, felids, and bovids [1]. *Sarcoptes* mites recovered from different hosts are indistinguishable morphologically, and genetic analyses show that the genus *Sarcoptes* contains a variable single species with several host-adapted strains [1]. Clinically, sarcoptic mange is characterized by severe pruritus, papules, alopecia, crusts, excoriations, and lichenification [2-9], which may become generalized in chronic cases, but typically, lesions concentrate at elbows, hocks, pinnal margins, and ventral abdomen [10]. Infestations are most common in crowded, unclean settings, where they are highly contagious. The mite is difficult to diagnose unless the animal is heavily infested, most tests lack sensitivity, and superficial skin scrapings may yield mites only 20% of the time [3].

The southern tamandua, or lesser anteater (*Tamandua tetradactyla*), is a forest-dwelling species native to South America [11]. Common typical ectoparasites are ticks, psoroptid mites, and fleas [12-14]. Tamanduas are frequently exhibited in zoos, and less commonly, owned privately as pets. The capybara (*Hydrochoeris hydrochaeris*) is a large rodent inhabiting riverbanks and marshlands in Central and South America. They also are common in zoos or privately owned for exhibition. At least 19 tick species

infest wild capybaras, and captive animals commonly sustain sarcoptic mange [2,7].

Case 1

A 3-year-old female intact southern tamandua presented for a 3-week history of pruritus and an exudative excoriation on the right flank. The animal was housed in a 2 × 1 × 2 m wire cage with aluminum flooring, bedded with pine shavings. The patient’s cage was kept in a room shared with a capybara but these animals never contacted each other directly. On physical examination, multifocal crusts and scale were observed at the base of the pinnae, axillae, elbows, and inguinal region. A 4 × 4 cm erythematous excoriated patch on the right flank (Figure 1) exuded serosanguinous discharge centrally, with peripheral crusting. The interdigital spaces were severely erythemic and moist. Patchy hypotrichosis was noted in the interscapular space, over the right shoulder, and on the dorsal surface of the muzzle. The patient was observed to be pruritic during the examination. An impression smear was acquired from the right flank. Hair was plucked from multiple areas for trichogram, and a sample for dermatophyte fungal culture was acquired via the McKensie toothbrush technique. A crust at the cranial margin of the excoriation was lifted and the area underneath swabbed for bacterial and fungal cultures. Skin scrapings were performed at multiple affected sites.

Skin cytology revealed neutrophilic inflammation, with intra and extracellular coccoid and rod-shaped bacteria. No parasites or fungal agents were observed on trichogram, and dermatophyte test media revealed no growth after one month. Bacterial culture revealed heavy growth of several species, including Staphylococcus aureus, Proteus mirabilis, Corynebacterium spp., and two species of Streptococcus, while fungal culture yielded a heavy growth of Candida albicans. Skin scrapings taken from the right elbow and right inguinal fold revealed heavy growth of Sarcoptes scabiei. No parasites or fungal agents were observed on trichogram, and dermatophyte test media revealed no growth after one month. Bacterial culture revealed heavy mixed growth of several species, including Staphylococcus aureus, Proteus mirabilis, Corynebacterium spp., and two species of Streptococcus, while fungal culture yielded a heavy growth of Candida albicans. Skin scrapings taken from the right elbow and right inguinal fold revealed heavy growth of Sarcoptes scabiei. Skin scrapings were performed at multiple affected sites.

Skin cytology revealed neutrophilic inflammation, with intra and extracellular coccoid and rod-shaped bacteria. No parasites or fungal agents were observed on trichogram, and dermatophyte test media revealed no growth after one month. Bacterial culture revealed heavy growth of several species, including Staphylococcus aureus, Proteus mirabilis, Corynebacterium spp., and two species of Streptococcus, while fungal culture yielded a heavy growth of Candida albicans. Skin scrapings taken from the right elbow and right inguinal fold revealed heavy growth of Sarcoptes scabiei. Skin scrapings were performed at multiple affected sites.

For treatment of presumed opportunistic bacterial skin infection, Selamectin (Revolution, Zoetis Inc., Kalamazoo, Michigan 49007, USA; 9 mg/kg topically, once), was applied between the shoulders, with an additional dose for owner-applied retreatment in two weeks. Repeat skin scraping was planned four weeks after initial examination, but the tamandua died due to unknown causes three weeks after evaluation. A necropsy was performed, but poor post-mortem preservation of the body allowed marked autolysis and prevented accurate determination of death.

Case 2

A 3-year-old intact female capybara presented for pruritus of two weeks duration. This patient was owned and housed as described in Case 1, but it was examined six weeks later. On examination, the capybara was diffusely erythemic with generalized scale. Multifocal crusts and patches of hyperkeratosis were present along the venter, with excoriations on the face and flanks. The patient was emaciated and had mucopurulent nasal discharge (Figure 2). Skin scrapings from the ventral chest, left periorcular region, and left elbow yielded numerous live suspected S. scabiei. Subsequent standard tissue maceration, flotation, and microscopic examination of slide-mounted mites (Figure 3) confirmed the identification. Other skin scrapings were collected for molecular analysis. The capybara was treated with selamectin (Zoetis; 9 mg/kg topically, once) and the owner repeated treatment in two weeks. The capybara also was treated for respiratory disease with enrofloxacin (Baytril, Bayer Animal Health, Shawnee Mission, Kansas 66216, USA; 15 mg/kg p.o., b.i.d. for two weeks). There was no follow-up appointment, but per client telephone communication three months later, pruritus and skin lesions resolved after two selamectin treatments, and the patient remained symptom-free.

DNA was extracted from skin scrapings obtained from both hosts, using the DNeasy Blood and Tissue Kit (QIAGEN Inc., Valencia, California 91355, USA) and following manufacturer’s protocol. DNA was eluted in 200 µL of water and stored at -20°C. 700 base pairs of the mitochondrial cytochrome C oxidase subunit 1 (COX1) were amplified in 50 µL reactions, using 2 µL of DNA, 3 mmol...
of MgCl₂, 200 µmol of dNTPs, 1x PCR buffer, 2 units of Taq DNA Polymerase (Promega Corp., Madison, Wisconsin 53704, USA), and 2.5 µmol each of primers 5'-GACACCCAAGTTACATTCT-3' and 5'-TATATTTGATAATGAATCTC-3' [6]. Thermocycling conditions with denaturation at 94°C for 2 min, 5 cycles of 94°C for 15 s, 45°C for 15 s, 72°C for 1 min, followed by 30 cycles of 94°C for 15 s, 50°C for 15 s, 72°C for 1 min, and a final extension step of 72°C for 5 min.

Presence of amplification products was confirmed with agarose gel electrophoresis on 1.5% gels. Products were purified using the Wizard SV Gel and PCR Clean-Up System (Promega). Sequencing was performed on an Applied Biosystems 3730 xl DNA Analyzer. Trimming and pairwise sequence alignments were conducted using MEGA6.06 [13]. Nucleotide BLAST searches were performed to compare sequences with those in NCBI GenBank. Sequences were deposited in GenBank (BankIt1952082). Partial Cox1 sequences obtained after sequencing were trimmed to 543 bp. Pairwise sequence alignment of the partial Cox1 gene of Sarcoptes derived from both hosts revealed 100% mutual identity. BLAST results revealed that the sequences had 99.63% identity with S. scabiei types suis and canis; 99.44% identity with S. scabiei types vulpes, wallaby and wombat; 99.26% identity with S. scabiei types hominis and oryctolagus 2; and 99.08% identity with S. scabiei type oryctolagus 2.

This report describes the first documented case of sarcoptic mange in any anteater and the evident transmission of mites between a captive capybara and a tamandua. Despite unsubstantiated generic mentions of S. scabiei from anteaters in two review papers, [4,8] there are no previous, verified primary reports of sarcoptic mange in any member of the Vermilingua, associated with sarcoptic mange. Circumstances suggest that these mites can be transmitted between proximately housed host species, and they may have further zoonotic potential. Topical treatment with selamectin may provide a viable treatment option in future cases.
