Development of an Ultrasonic Method to Detect Cervical Remodeling in Vivo in Full-Term Pregnant Women

Abstract
The objective of this study was to determine whether estimates of ultrasonic attenuation could detect changes in the cervix associated with medically induced cervical remodeling. Thirty-six full-term pregnant women underwent two transvaginal ultrasonic examinations separated in time by 12 h to determine cervical attenuation, cervical length and changes thereof. Ultrasonic attenuation and cervical length data were acquired from a zone (Zonare Medical Systems, Mountain View, CA, USA) ultrasound system using a 5–9 MHz endovaginal probe. Cervical attenuation and cervical length significantly decreased in the 12 h between the pre-cervical ripening time point and 12 h later. The mean cervical attenuation was 1.1 ± 0.4 dB/cm-MHz before cervical ripening agents were used and 0.8 ± 0.4 dB/cm-MHz 12 h later (p < 0.0001). The mean cervical length also decreased from 3.1 ± 0.9 cm before the cervical ripening was administered to 2.0 ± 1.1 cm 12 h later (p < 0.0001). Cervical attenuation and cervical length detected changes in cervical remodeling 12 h after cervical ripening administration.

Introduction

Globally, over 13 million infants are born preterm each year (Harris-Requejo 2010). Preterm birth is defined as birth before 37 completed weeks of pregnancy (Martin et al. 2009). Spontaneous preterm labor is a syndrome associated with multiple etiologies of which only a percentage may be associated with cervical insufficiency (Romero et al. 2006). Regardless of the etiology of preterm labor, the cervix must remodel to allow the passage of the fetus. The role of the cervix during pregnancy is to maintain the fetus within the uterine cavity until fetal maturity. The strength of the cervix is due to its anatomic properties (length, thickness) and tissue composition (collagen, water and extracellular matrix) (House and Socrate 2006).

Most of our understanding of cervical remodeling in pregnancy is from animal studies and very few human studies. Thus, we describe a widely accepted hypothesis of the process of cervical remodeling in human pregnancy based upon the available evidence (Danforth 1947; Leppert 1995; Owen and Iams 2003; Romero et al. 2006; Word et al. 2007; Feltovich et al. 2010). During pregnancy, total cervical collagen content increases to provide strength to the cervix (Harkness and Nightingale 1962; Golichkowski et al. 1980; Kokenyesi and Woessner 1990; Eckman et al. 1991; Woessner and Kokenyesi 1991; Yu and Leppert 1991). Before the onset of labor contractions and over a period of weeks, the cervix remodels through a process of collagen disorganization (Weiss 2000; House and Socrate 2006; Vidaeff and Ramin 2006a; Vidaeff and Ramin 2006b) wherein water content and proteoglycans are increased, and collagen concentration is decreased (Danforth et al. 1960; Golichkowski et al. 1980; Yu and Leppert 1991; Leppert et al. 2000; Feltovich et al. 2005; McFarlin et al. 2006), thus resulting in increased extensibility and reduced stiffness of the cervix. During this process, increased space results among the collagen fibrils (Leppert and Yu 1991; Leppert 1995; Leppert et al. 2000; Feltovich et al. 2005; Clark et al. 2006). The biostructure, biochemistry and biomechanics of the cervix change markedly from an unripe to a ripe cervix (Leppert 1995; Leppert et al. 2000; Lawn et al. 2010; Mahmoud et al. 2013).

Currently, the most powerful risk factors for preterm birth are assessed by patient history of a prior preterm birth and from a shortened length of the cervix at around 20 weeks of pregnancy. There is a approximately a 40% recurrence of preterm birth in women with a prior history of preterm birth (Iams and Berghella 2010). Although cervical length assessment has become one of the most widely used tools to identify women at high risk for preterm birth, it has low positive predictive value in low-risk women because the majority of individuals identified with a short cervix still deliver at term (Berghella et al. 2009; Romero et al. 2013). In women at low risk for preterm birth, the positive predictive value of cervical length to predict spontaneous preterm birth ranges from 20 to 52% (Romero et al. 2013). Generally, the shorter the cervix, the greater the probability of preterm birth (Iams and Berghella 2010; Campbell 2011; Romero et al. 2013). There has been considerable work by our group (McFarlin et al. 2006; Bigelow et al. 2008; McFarlin et al. 2010; Bigelow et al. 2011; Labyed and Bigelow 2011a; Labyed et al. 2011; Lau et al. 2013; Poellmann et al. 2013) and others (House and Socate 2006; Feltovich et al. 2010; Feltovich et al. 2012; House et al. 2012; Feltovich and Hall 2013; Carlson et al. 2014) to develop noninvasive
methods to detect and understand cervical microstructural tissue properties associated with cervical remodeling.

Presently an *in vivo*, objective and noninvasive clinical method to determine tissue changes (increased collagen disorganization and water concentration) associated with cervical remodeling does not exist. Our research has sought to develop an ultrasonic method that could be correlated with changes associated with cervical remodeling, and potentially associated with preterm birth. We have translated promising basic science ultrasonic methods we used in an animal model (Bigelow et al. 2005; Bigelow and O’Brien 2006; McFarlin et al. 2006; Bigelow et al. 2008; Labyed and Bigelow 2011a; Labyed et al. 2011) for use in human pregnancy (McFarlin et al. 2006; Bigelow et al. 2008; McFarlin et al. 2010; Bigelow et al. 2011; Labyed and Bigelow 2011a; Labyed et al. 2011; Lau et al. 2013; Poellmann et al. 2013).

Estimates of ultrasonic attenuation have been used to evaluate the structure and function of tissue in health and disease (Insana et al. 1992; Wickline et al. 1992a; Wickline et al. 1992b; Insana 1995; O’Brien et al. 1995; Hall et al. 2000a; Hall et al. 2000b; Hall et al. 2000c; Baldwin et al. 2007). Ultrasonic attenuation has been found to be related to tissue stiffness, collagen content and organization and water concentration of tissues (Hall et al. 1997; Hall et al. 2000a; Hall et al. 2000b; Hall et al. 2000c; Baldwin et al. 2007), and also has been shown to be higher in collagen rich tissues such as a tendon (O’Brien 1977) and rat cervix (Bigelow et al. 2008) compared to low collagen content tissues, such as fat (O’Brien 1977). In pregnancy, as the collagen-rich cervix remodels to prepare for labor and birth, the cervix transforms from a rigid structure to a soft, extensible structure (Leppert 1995; House and Socrate 2006). We hypothesized that by estimating changes in cervical ultrasonic attenuation we could detect and monitor these dynamic changes in tissue microstructure and function.

Our prior animal model work demonstrated that the decreased collagen concentration associated with cervical remodeling affected ultrasonic attenuation (McFarlin et al. 2006; Bigelow et al. 2008). We found that estimates of cervical attenuation were significantly correlated with gestational age in the rat cervix as ripening occurred (McFarlin et al. 2006; Bigelow et al. 2008; Bigelow et al. 2011). In a small methodology development study of the human pregnant cervix, we were able to acquire and analyze backscattered radio frequency (RF) ultrasonic signals to estimate attenuation as the cervix remodeled (McFarlin et al. 2010). There was a statistically significant relationship between decreasing attenuation and interval to delivery (McFarlin et al. 2010). Women who delivered preterm had lower cervical attenuation values than those who delivered full term. The long-term goal of our program of research is to use ultrasonic attenuation to identify women at risk for preterm birth. Ultrasonic attenuation is a feature that could be incorporated into clinical ultrasound systems.

During pregnancy when labor must be medically induced, mechanical and pharmacological agents such as prostaglandins and cervical balloons can accelerate the process of cervical remodeling before inducing labor contractions (Boulvain et al. 2008). Prostaglandins have produced marked cervical remodeling changes in times as small as five to twelve hours...
(Leppert 1995; Calder et al. 2008). As a proof-of-concept study, our objective herein was to
determine whether cervical attenuation was sensitive to cervical remodeling associated with
medically induced cervical remodeling, a known process where cervix tissue remolds in a
short time frame of 12 hours rather than over many weeks during pregnancy and
spontaneous labor. Our hypothesis was that a significant decrease in cervical attenuation
occurs after a ripening agent was administered.

**Materials and Methods**

Thirty-six pregnant women who were admitted for induction of labor were recruited for the
study. Women were eligible to be included in the study if they were: ≥ 18 years of age; able
to read, write and understand English; going to receive a prostaglandin cervical ripening
agent for induction of labor; and agreed to twice undergo transvaginal ultrasonic
examinations during labor induction. We chose to study women receiving prostaglandin
cervical ripening agents for induction of labor, as marked change in cervical remodeling is
known to occur within 12 hours (Facchinetti et al. 2012). Women were excluded from
participating in the study if they had an anomalous fetus or were too ill to give informed
consent. Women were recruited once they were admitted to the Labor and Delivery unit.
None of the women underwent induction of labor for the purposes of this research. The
research was approved by the Human Subjects Review Boards of the University of Illinois
at Chicago and Rush University Medical Center. An informed consent statement was signed
by each woman participating in the study.

Thirty-six women agreed to participate in the study and underwent a transvaginal ultrasonic
examination with a standard 5–9 MHz endovaginal transducer to estimate ultrasonic
attenuation and cervical length before cervical ripening agents were administered and then
scanned again 12 hours after cervical ripening agents were administered. Immediately after
each cervical scan, and without changing any scanner settings, a reference scan was
recorded in a well-characterized, tissue-mimicking reference phantom with known
ultrasonic properties (sound speed, attenuation coefficient, backscatter coefficient) that were
comparable to average human tissue.

Cervical length was measured according to the standard method developed by Iams (Iams et
al. 1996). The length of the cervix was measured with the transvaginal ultrasound probe
placed in the anterior fornix of the vagina while the woman’s bladder was empty. Without
placing pressure on the cervix, a sagittal image of the cervix was obtained where the internal
and external os were present. The cervix was measured three times along the line made by
the interface of the mucosal surfaces. The shortest cervical length was recorded.

The steps for processing the data are summarized in Figure 1. In-phase Quadrature (IQ) data
were obtained from z.one ultrasound system (Zonare Medical Systems, Mountain View,
CA) and converted to RF data (bandwidth: 3.4–7.1 MHz). The IQ data contained scans of
the cervix and reference phantom. A Gammex® tissue-mimicking phantom (Gammex®,
Middleton, WI) with a known attenuation of 0.5 dB/cm-MHz was used as a reference
phantom.
The RF echo data from the cervix were windowed into smaller regions of interest (sub-ROIs), and the attenuation was estimated for each sub-ROI to represent a spatial map of the attenuation throughout the closed portion of the cervix. Early in our methodology (McFarlin et al. 2010), we selected the most homogeneous appearing area of the cervix. However, we were concerned about sub-ROI selection bias and reproducibility of the measure. Thus, our approach with this and follow-up studies has been to map the entire closed portion of the cervix and use a mean attenuation value from all of the sub-ROIs as the cervical attenuation.

The spectral log difference method was used to estimate the attenuation by calculating the slope of the straight line that fits the log ratio (difference between log spectra) of the two power spectra (cervix and reference phantom spectra) from the proximal and the distal segments of the sub-ROIs (Labyed and Bigelow 2011b). The spectral log difference method is one that is least susceptible to tissue heterogeneity as was observed in our previous studies (Bigelow et al. 2011; Labyed and Bigelow 2011b). Our criterion for selecting the size of the sub-ROIs was to have enough tissue to make attenuation estimates with the least error, and at the same time minimize the heterogeneity of the tissue included in the sub-ROI. Figure 2 displays an attenuation image (a spatial map of the sub-ROIs) of the cervix that shows consistency with known tissue layers of the human cervix (Leppert 1995). For example, the image shows the attenuation of the cervical mucus layer to be essentially zero (Aisemberg et al. 2013), which is consistent with the known attenuation of water (Shung et al. 1992), while the tissue layers in the cervix have an attenuation range from 0 to 2.5 dB/cm-MHz.

We evaluated the inter-rater reliability of attenuation mapping of the cervix by having 50% of the scans mapped and reprocessed independently by a second examiner and found an inter-rater reliability of $r = 0.97$, $p < 0.001$. All data were entered into an electronic database and analyzed with IBM SPSS 19.0 (Armonk, NY) statistical software. Analysis included descriptive statistics, paired two-tailed $t$ tests, Pearson correlation and ANOVA. $\alpha < 0.05$ was considered significant.

**Results**

The thirty-six women participating in the study were at full term pregnancy ($\geq$39 weeks of gestation). Table 1 displays maternal characteristics of study participants. Elective induction of labor, and post-dates pregnancy were the most common indications listed for labor induction. While the majority of women in the study delivered vaginally, 16 (44%) delivered by cesarean section. There was no significant difference in attenuation and cervical length at each time point among the women delivering vaginally or by cesarean (Table 2). The main indication for cesarean section was arrest of labor.

Figure 3 displays individual attenuation (Fig. 3A) and cervical length (Fig. 3C) outcomes. The women who had the highest attenuation at the pre-cervical ripening time point were those who also had the greatest decrease in attenuation at the second scan 12 hours later. Initial attenuation values pre- and post-cervical ripening were similar among nulliparous and multiparous women (Fig. 3B). Cervical attenuation significantly decreased ($p<0.0001$) in the 12 hours between the pre-cervical ripening attenuation time point and 12 hours later. The mean cervical attenuation of these full term women was $1.1\pm0.4$ dB/cm-MHz before
cervical ripening agents were used and 0.8±0.4 dB/cm-MHz 12 hours later. Thus, by using ultrasonic attenuation, we were able to detect changes in cervical remodeling in a short period of time, suggesting that ultrasonic attenuation is sensitive to tissue property changes.

As expected, mean cervical length also decreased from 3.1±0.9 cm before the cervical ripening was administered to 2.0 ±1.1 cm 12 hours later, \( p < 0.0001 \). Pre-cervical ripening, cervical length ranged from 2.0 to 5.5 cm (Fig. 3C). Initial cervical lengths pre- and post-cervical ripening were similar among nulliparous and multiparous women (Fig. 3D). There was no correlation between cervical attenuation and cervical length, suggesting that these measures may be independently detecting structures in the cervix.

Discussion

In this study, we were able to detect changes in ultrasonic attenuation of the cervix at 12 hours after a cervical ripening agent was administered. Our previous work found a relationship between cervical tissue properties and attenuation (McFarlin et al. 2006; McFarlin et al. 2010; Labyed et al. 2011). Interestingly, ultrasonic attenuation was not correlated with cervical length, thus suggesting that cervical attenuation and cervical length are likely independent measures because each may be sensitive to different structures and/or spatial scales of the cervix. One can think about spatial scales between cervical attenuation and cervical length. Ultrasonic attenuation is a measure of cervical tissue at a scale of around the ultrasonic wavelength, that is, about 300 μm and is affected by tissue hydration and density. For example, the attenuation of water and cervical mucus is about 0 dB/cm-MHz (see Figure 2). On the other hand, ultrasonic cervical length is a measure at a larger scale, around a couple of centimeters (about 100 times greater than the ultrasonic wavelength). It is not surprising that the attenuation coefficient ranges from 0 to 2.5 dB/cm-MHz; cervical tissue is heterogeneous in nature (Feltovich et al. 2010; Lau et al. 2013).

Thus, to address the heterogeneity issue we averaged all of the attenuation values within the selected portion of the cervix.

Both cervical length and attenuation decreased significantly from the initial scan to the scan 12 hours after a cervical ripening agent was administered. We hypothesized that there would be a significant decrease in cervical attenuation after the cervix was exposed to a ripening agent. We did not power the study or was it our intention in this study to use this technology to predict mode of delivery (cesarean or vaginal birth). Cervical remodeling is only one factor when determining whether a woman will deliver vaginally or by cesarean. Factors such as the size and position of the fetus, size of the maternal pelvis, strength of uterine contractions, and fetal tolerance of labor also need to be clinically considered.

Our previous animal study results indicated: a decrease in attenuation with gestational age of rat pregnancy; marked cervical collagen content and water increase in pregnancy; and increased collagen disorganization during the process of cervical remodeling. In human pregnancy (McFarlin et al. 2006; Bigelow et al. 2011), ultrasonic attenuation has been related to the number of weeks to delivery and risk of preterm birth in a pilot study (McFarlin et al. 2010). The attenuation values in this study are similar to attenuation values during pregnancy in our previous study (McFarlin et al. 2010). Thus, ultrasonic attenuation
may have the potential to be an additional objective measure of cervical tissue remodeling. Although macro structural changes of the cervix can be quantified with cervical length (Iams et al. 1996; Berghella et al. 2009; Iams and Berghella 2010; Romero et al. 2013) and cervical consistency index (Parra-Saavedra et al. 2011), there is currently no method to objectively estimate cervical tissue property changes noninvasively.
