Photoproduction of J/psi and of high mass e(+)e(-) in ultra-peripheral Au plus Au collisions at root s(NN)=200 GeV

Abstract
We present the first measurement of photoproduction of J/psi and of two-photon production of high-mass e(+)e(-) pairs in electromagnetic (or ultra-peripheral) nucleus-nucleus interactions, using Au + Au data at root s(NN) = 200 GeV. The events are tagged with forward neutrons emitted following Coulomb excitation of one or both Au* nuclei. The event sample consists of 28 events with m(e+e-) > 2 GeV/c(2) with zero like-sign background. The measured cross sections at midrapidity of d sigma/dy (J/psi + Xn, y = 0) = 76 +/- 33 (stat) +/- 11 (syst) pb and d(2)sigma /dm dy (e(+) e(-) + Xn, y = 0) = 86 +/- 23(stat) +/- 16(syst) mu b/ (GeV/c(2)) for m(e+e-) epsilon vertical bar 2.0, 2.8 vertical bar GeV/c(2) have been compared and found to be consistent with models for photoproduction of J/psi and QED based calculations of two-photon production of e(+)e(-) pairs.

Photoproduction of $J/\psi$ and of high mass $e^+e^-$ in ultra-peripheral Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV

PHENIX Collaboration

We present the first measurement of photoproduction of J/ψ and of two-photon production of high-mass J/ψ+e+e− pairs in electromagnetic (or ultra-peripheral) nucleus–nucleus interactions, using Au+Au data at √sNN = 200 GeV. The events are tagged with forward neutrons emitted following Coulomb excitation of one or both Au nuclei. The event sample consists of 28 events with \( \sigma/J_\gamma \times dN_{\rm Xn}/dy \geq 2 \) with zero like-sign background.
1. Introduction

The idea to use the strong electromagnetic fields present in high-energy nucleus–nucleus collisions to study photoproduction at hadron colliders has attracted growing interest in recent years, see [1–3] for reviews. Electromagnetic interactions can be studied without background from hadronic processes in ultra-peripheral collisions (UPC) without nuclear overlap, i.e. impact parameters larger than the sum of the nuclear radii. This study focuses on the measurement of exclusively produced high-mass $e^+ e^-$ pairs at midrapidity in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. $\bar{A} + A \rightarrow A + \bar{A} + e^+ e^-$. The results have been obtained with the PHENIX detector [4] at the BNL Relativistic Heavy Ion Collider (RHIC).

The electromagnetic field of a relativistic particle can be represented by a spectrum of equivalent photons. This is the Weizsäcker–Williams method of virtual quanta [5,6]. The number of photons in the spectrum is proportional to $Z^2$, where $Z$ is the charge number of the particle, and the equivalent two-photon luminosity is thus proportional to $Z^4$. The strong dependence on $Z$ favours the use of heavy ions for studying two-photon and photoproduction processes. The virtualizations of the equivalent photons when the field couples coherently to the entire nucleus are restricted by the nuclear form factor to $Q^2 = (\omega^2/(cy)^2 + q_z^2) < (h/\lambda R)^2$. Here, $\omega$ and $q_z$ are the photon energy and transverse momentum, respectively, $\lambda R$ is the nuclear radius and $\gamma$ the Lorentz factor of the beam. At RHIC energies, $\gamma = 108$ and the maximum photon energy in the center-of-mass system is of the order of $\omega_{\text{max}} \sim 3$ GeV corresponding to maximum photon–nucleon and two-photon center-of-mass energies of $W^\gamma_{\text{max}} \sim 34$ GeV and $W^\gamma_{\text{max}} \sim 6$ GeV.

The exclusive production of an $e^+ e^-$ pair can proceed either through a purely electromagnetic process (a two-photon interaction to leading order) or through coherent photonuclear production of a vector meson, which decays into an electron pair. Exclusive photoproduction of vector mesons is usually thought of as proceeding via Pomeron-exchange, the perturbative-QCD equivalent of which is the exchange of two gluons or a gluon ladder. The Feynman diagrams for the two leading order processes are shown in Fig. 1. The two-gluon picture is applicable to production of heavy vector mesons, such as the $J/\psi$, and to production of lighter mesons at high momentum transfers [7]. The $J/\psi$ production cross section is consequently a good probe of the production [8] and nuclear gluon distribution, $G_G(x, Q^2)$, as well as of vector-meson dynamics in nuclear matter [9,10]. For $J/\psi$ photoproduction, the coverage of the PHENIX central tracking arm, $-0.35 < \eta < 0.35$ corresponds to a range in the photon–nucleon center-of-mass energy between $21 < W^\gamma_{\text{NN}} < 30$ GeV, with a mean $(W^\gamma_{\text{NN}}) = 24$ GeV. This corresponds to photon energies in the rest frame of the target nucleus of $240 < E_\gamma < 480$ GeV, with $(E_\gamma) = 300$ GeV. Mid-rapidity photoproduction of $J/\psi$ probes nuclear Bjorken-$x$ values of $x = m_{J/\psi}^2 / W^2 \gamma_{\text{stat}} \sim 1.5 \times 10^{-2}$ [10], where the nuclear gluon density is partially depleted by “shadowing” effects [11] compared to the proton.

The strong fields associated with heavy ions at high energies lead to large probabilities for exchanging additional soft photons in the same event. Most of these photons have too low energy to produce particles, but they can excite the interacting nuclei. The dominating excitation is to a Giant-Dipole Resonance (GDR) with energies $\mathcal{O}(10 \text{ MeV})$, which decays by emitting neutrons at very forward rapidities, providing a very useful means to trigger on UPCs with Zero-Degree Calorimeters (ZDC). The probability for having a Coulomb excitation leading to emission of neutrons in at least one direction in coincidence with coherent $J/\psi$ production is $55 \pm 6\%$ [12]. The probabilities for exchanging one or several photons factorise, i.e. the Coulomb tagging does not introduce any bias in the extraction of exclusive $J/\psi$ photoproduction cross sections from these events [13]. The soft photons leading to moderate nuclear excitation are indicated to the right of the dashed line in Fig. 1. Incoherent (or quasi-elastic) vector-meson photoproduction can also proceed via the interaction of the exchanged photon with a single nucleon in the nucleus. In that case, $J/\psi$ photoproduction is always accompanied by nuclear breakup and emission of nucleons in the forward direction [14].

Photoproduction of vector mesons has been studied with lepton beams first in the 60s [15,16] and more recently at the electron–proton collider HERA [17,18]. Measurements of photonuclear production of $\rho$ mesons [19,20], as well as two-photon production of low-mass $e^+ e^-$ pairs [21] in heavy ion interactions have been performed by the STAR Collaboration. The CDF Collaboration has studied two-photon production of $e^+ e^-$ pairs [22] and exclusive production of $\mu^+ \mu^-$ pairs [23] in $p p$ collisions at the Tevatron. The PHENIX analysis presented here is the first on heavy final states in ultra-peripheral nucleus–nucleus collisions. It supersedes a preliminary study presented earlier [24]. The cross section for $J/\psi$ and $e^+ e^-$ photoproduction are compared with various theoretical calculations [10,14,25–27].

2. Experimental setup

The data presented here were collected with the PHENIX detector at RHIC during the 2004 high-luminosity $\bar{A} + A$ run at $\sqrt{s_{NN}} = 200$ GeV. The PHENIX detector [4], is a versatile detector designed to study the properties of strongly interacting matter at extreme temperatures and energy densities present in central heavy ion collisions. The current analysis demonstrates its capabilities to also study ultra-peripheral collisions, which have a very different event topology. The PHENIX central tracking system [28] consists of two arms, each covering $|\eta| < 0.35$ and $\Delta \phi = \pi/2$, equipped with multi-layer drift chambers (DC) followed by multi-wire proportional chambers (PC) with pixel-pad readout. The tracking arms also have Ring-Imaging-Cherenkov (RICH, with CO$_2$ gas radiator) detectors [29] and electromagnetic calorimeters (EMCal) [30] for electron and positron identification. The PHENIX EMCal consists of six sectors of lead-scintillator sandwich calorimeter (PbSc, 15552 individual towers with $5.54 \times 5.54 \times 37.5$ cm,
triggered events. and cover with the following characteristics:

- The ultra-peripheral Au + Au events were tagged by neutron detection at small forward angles in the ZDC. The ZDCs \([31,32]\) are hadronic calorimeters placed 18 m up- and down-stream of the detection at small forward angles in the ZDC. The ZDCs are 324 modules with 4 cm \(\times\) 4 cm \(\times\) 40 cm, 14.4 \(X_0\), at a radial distance of \(\sim 5\) m from the beam line.

The ultra-peripheral Au + Au events were tagged by neutron detection at small forward angles in the ZDC. The ZDCs \([31,32]\) are hadronic calorimeters placed 18 m up- and down-stream of the interaction point that measure the energy of the neutrons coming from the Au\(^+\) Coulomb dissociation with \(\sim 20\%\) energy resolution and cover \(|\theta| < 2\) mrad, which is a very forward region.\(^3\)

The events used in this analysis were collected with the UPC trigger set up for the first time in PHENIX during the 2004 run with the following characteristics:

1. A veto on coincident signals in both Beam–Beam Counters (BBC, covering 3.0 < |η| < 3.9 and full azimuth) selects exclusive-type events characterised by a large rapidity gap on either side of the central arm.
2. The EMCal-Trigger (ERT) with a 2 \(\times\) 2 tile threshold at 0.8 GeV. The trigger is set if the analog sum of the energy deposit in a 2 \(\times\) 2 tile of calorimeter towers is above threshold (0.8 GeV).
3. At least 30 GeV energy deposited in one or both of the ZDCs is required to select Au + Au events with forward neutron emission \(\langle X_n\rangle\) from the (single or double) Au\(^+\) decay.

The BBC trigger efficiency for hadronic Au + Au collisions is 92 \(\pm\) 3\% \([33]\). A veto on the BBC trigger has an inefficiency of 8\%, which implies that the most peripheral nuclear reactions could be a potential background for our UPC measurement if they happen to have an electron pair in the final state. An extrapolation of the measured p–p dielectron rate \([34]\) at \(m_{\text{inv}} > 2\) GeV/\(c^2\) to the 8\% most peripheral interactions – scaled by the corresponding number of nucleon–nucleon collisions (1.6) – results in a negligible contribution (only 0.4 \(e^+e^-\) pairs). On the other hand, the ERT trigger requirement (2) has an efficiency of 90 \(\pm\) 10\%, and the requirement (3) of minimum ZDC energy deposit(s) leaves about 55\% of the coherent and about 100\% of the incoherent J/ψ events, as discussed above. All these trigger efficiencies and their uncertainties are used in the final determination of the production cross sections below.

The total number of events collected by the UPC trigger was 8.5 M, of which 6.7 M satisfied standard data quality assurance criteria. The useable event sample corresponds to an integrated luminosity \(L_{\text{int}} = 141 \pm 12 \mu\text{b}^{-1}\) computed from the minimum bias triggered events.

\[^3\] Much larger than the crossing angle of Au beams at the PHENIX interaction point (0.2 mrad).

3. Data analysis

Charged particle tracking in the PHENIX central arms is based on a combinatorial Hough transform in the track bend plane (perpendicular to the beam direction). The polar angle is determined from the position of the track in the PC outside the DC and the reconstructed position of the collision vertex \([35]\). For central collisions, the collision vertex is reconstructed from timing information from the BBC and/or ZDC. This does not work for UPC events, which, by definition, do not have BBC coincidences and often do not have ZDC coincidences. The event vertex was instead reconstructed from the position of the PC hits and EMCal clusters associated with the tracks in the event. This gave an event vertex resolution in the longitudinal direction of 1 cm. Track momenta are measured with a resolution \(\delta p/p \approx 0.7\% \oplus 1.0\%[\text{GeV/c}]\) in minimum bias Au + Au nuclear collisions \([36]\). Only a negligible reduction in the resolution is expected in this analysis because of the different vertex resolution.

The following global cuts were applied to enhance the sample of genuine \(\gamma\)-induced events:

1. A standard offline vertex cut \(|v_x| < 30\) cm was required to select collisions well centered in the fiducial area of the central detectors and to avoid tracks close to the magnet poles.
2. Only events with two charged particles were analyzed. This is a restrictive criterion imposed to cleanly select “exclusive” processes characterised by only two isolated particles (electrons) in the final state. It allows to suppress the contamination of non-UPC (mainly beam–gas and peripheral nuclear) reactions that fired the UPC trigger, whereas the signal loss is small (less than 5\%).

Unlike the \(J/\psi \rightarrow e^+e^-\) analyses in nuclear Au + Au reactions \([36,37]\) which have to deal with large particle multiplicities, we did not need to apply very strict electron identification cuts in the clean UPC environment. Instead, the following RICH- and EMCal-based offline cuts were used:

1. RICH multiplicity \(n_0 \geq 2\) selects \(e^\pm\) which fire 2 or more tubes around the track within the nominal ring radius.
2. Candidate tracks with an associated EMCal cluster with dead or noisy towers within a 2 \(\times\) 2 tile are excluded.
3. At least one of the tracks in the pair is required to pass an EMCal cluster energy cut \((E_1 > 1\ \text{GeV} \parallel E_2 > 1\ \text{GeV})\) to select candidate \(e^\pm\) in the plateau region above the turn-on curve of the ERT trigger (which has a 0.8 GeV threshold).

Beyond those global or single-track cuts, an additional “coherent” identification cut was applied by selecting only those \(e^+e^-\) candi-
dates detected in opposite arms. Such a cut aims at reducing the high-$p_T$ pairs while improving the detection of the low-$p_T$ pairs expected for $\gamma \gamma$, $\gamma A$ production. Nevertheless, after all the previous cuts were applied the influence of this selection is found to be small; there is only one event in which the $e^+$ and $e^-$ are in the same arm and have $m_{e^+e^-} > 2 \text{ GeV}/c^2$.

Finally, $J/\psi$ were reconstructed by invariant mass analysis of the measured $e^+e^-$ pairs. There was no remaining like-sign background after the aforementioned analysis cuts.

The cross sections were obtained after correcting the raw number of signal counts for the geometrical acceptance of our detector system, and the efficiency losses introduced by the previously described analysis cuts. Acceptance and efficiency corrections were obtained using the PHENIX GEANT3 [38] simulation package with input distributions from the STARLIGHT Monte Carlo (MC), based on the models presented in [12,25,39]. The measured $\gamma + p \rightarrow V + p$ cross sections from HERA and fixed target experiments with lepton beams are used as input to the models. STARLIGHT well reproduces the existing $d^2N/d\phi d\phi_T$ distribution of coherent $\rho$ production in UPC $Au+Au$ events measured at RHIC by STAR [19,20]. Helicity conservation is assumed in the model, and the angular distribution of the decay products ($J/\psi \rightarrow e^+e^-$) is given by $dN/d\cos(\theta) \propto 1 + \cos^2(\theta)$ in the $J/\psi$ center-of-mass. The angular distribution is different from that for $\rho$ production followed by the decay $\rho \rightarrow \pi^+\pi^-$, because of the different spin of the daughters, as well as from the angular distribution in two-photon interactions $\gamma + \gamma \rightarrow e^+e^-$. We generated $5 \times 10^5$ coherent $J/\psi$ and $8 \times 10^6$ coherent high-mass $e^+e^-$ pairs ($m_{e^+e^-} > 1 \text{ GeV}/c^2$) in $Au+Au$ collisions accompanied by forward neutron emission. The simulated events were passed through the same reconstruction programme as the real data.

Table 1 summarises the $J/\psi$ and dielectron acceptance and efficiency correction factors obtained from our simulation studies. For instance, for $J/\psi$ photoproduction the correction is $1/(2.49 \pm 0.25\%)$, of which the experimental acceptance to detect the decay electron pair is about $5\%$ (for $J/\psi$ produced at $|y| < 0.35$). In the $\gamma \gamma \rightarrow e^+e^-$ sample, most of the electrons/positrons are emitted at very forward angles. The fraction of events with $|y_{\text{pair}}| < 0.35$ and $2.0 < m_{e^+e^-} < 2.8 \text{ GeV}/c^2$, where both the electron and positron are within $|y| < 0.35$ is $1.0\%$. The corresponding numbers for $2.0 < m_{e^+e^-} < 2.3 \text{ GeV}/c^2$ and $2.3 < m_{e^+e^-} < 2.8 \text{ GeV}/c^2$ are $1.1\%$ and $1.08\%$, respectively. The acceptance and efficiency corrections have a systematic uncertainty of $10\%$ resulting from the accuracy of the simulation to describe the detector, the electron identification parameters, and the event vertex position resolution.

4. Results and discussion

The measured $e^+e^-$ invariant mass distribution for the sample is shown in Fig. 2(a). The amount of background can be estimated from the number of like-sign events (i.e. events where two electrons or two positrons are reconstructed). We find no like-sign pairs for $m_{e^+e^-} > 2 \text{ GeV}/c^2$, compared with 28 events with an $e^+e^-$ pair with $m_{e^+e^-} > 2 \text{ GeV}/c^2$. The shape is consistent with the expected contribution from the two processes in Fig. 1: a continuum distribution corresponding to two-photon production of $e^+e^-$ pairs and a contribution from $J/\psi \rightarrow e^+e^-$. Since the offline cuts ($E_1 > 1 \text{ GeV} \parallel E_2 > 1 \text{ GeV}$) cause a sharp drop in the efficiency for $m_{e^+e^-} < 2 \text{ GeV}/c^2$, we include only pairs with $m_{e^+e^-} > 2 \text{ GeV}/c^2$ in the analysis.

The invariant mass distribution is fitted with a continuum (exponential) curve combined with a Gaussian function at the $J/\psi$ peak, as shown by the solid curve in Fig. 2(a). Simulations based on events generated by the STARLIGHT MC (see last paragraphs of Section 3) processed through GEANT have shown that the shape of the measured continuum contribution is well described by an exponential function $dN/dm_{e^+e^-} = A \cdot e^{-m_{e^+e^-}}$. Those simulations allow us to fix the exponential slope parameter to $c = -1.9 \pm 0.1 \text{ GeV}^{-1} c^2$. The combined data fit is done with three free parameters: the exponential normalisation ($A$), the $J/\psi$ yield and the $J/\psi$ peak width (the Gaussian peak position has been fixed at the known $J/\psi$ mass of $m_{J/\psi} = 3.097 \text{ GeV}/c^2$ [40]). Fig. 2(b) shows the resulting invariant mass distribution obtained by subtracting the fitted exponential curve of the dielectron continuum from the

![Figure 2](image-url)
total experimental $e^+e^-$ pairs distribution. There is a clear $J/\psi$ peak, the width of which ($\sigma_{J/\psi} \sim 155$ MeV/$c^2$) is consistent with the $J/\psi$ width from our full MC.

The $J/\psi$ and continuum yields and the corresponding statistical errors are calculated from the fit. The dashed curves in Fig. 2(a) show the maximum and minimum $e^+e^-$ continuum contributions considered, including both the statistical and systematical uncertainties. The systematical uncertainties were determined varying the dielectron continuum subtraction method using a power-law form instead of an exponential function and by modifying the corresponding fitted slope parameters by $\pm 3\sigma$. The propagated uncertainty of the extracted yields was estimated to be one count in both cases. The total number of $J/\psi$’s is: $N_{J/\psi} = 9.9 \pm 4.1$ (stat) + 1.0 (syst), and the number of $e^+e^-$ continuum pairs for $m_{e^+e^-}$ in [2.0, 2.8] GeV/$c^2$ is: $N_{e^+e^-} = 13.7 \pm 3.7$ (stat) + 1.0 (syst). Table 2 shows the obtained results per invariant mass range.

Fig. 3(a) shows a scatter plot of invariant mass $m_{e^+e^-}$ vs. pair $p_T$. From the plot, it is clear that most of the pairs outside the $J/\psi$ peak originate in coherent processes with very low pair transverse momenta ($p_T \lesssim 100$ MeV/$c$), as expected for two-photon interactions. For events with $m_{e^+e^-}$ around the $J/\psi$ mass, however, there are a few counts at larger $p_T$ values which can be ascribed neither to the experimental $p_T$ resolution nor to background events, since there are no like-sign pairs above 2 GeV/$c^2$. A purely coherent production – corresponding to events where the fields couple coherently to all nucleons and the nucleus remains in its ground state ($\gamma + A \rightarrow V + A$) – would yield $p_T \lesssim 200$ MeV/$c$ after reconstruction. On the other hand, incoherent production ($\gamma + A \rightarrow V + X$) dominated by the quasi-elastic vector meson production off one nucleon inside the nucleus, $\gamma + N \rightarrow V + N$ – results in much larger $p_T$ for the photoproduced $J/\psi$ [14]. The cross sections for coherent and incoherent $J/\psi$ photoproduction in UPCs at RHIC are expected to be of the same order [14]. We discuss below whether our data confirm such a prediction.

The transverse momentum distribution of the events with $m_{e^+e^-} > 2$ GeV/$c^2$ is shown in Fig. 3(b). For clarity, only points below $p_T < 1$ GeV/$c$ are drawn. The $p_T$ is here the magnitude of the vector sum of the $p_T$ of the electron and positron. One sees a

The correction factors (and corresponding uncertainties) are quoted in Table 1 as described in previous sections, and BR = 5.94% is the known $J/\psi$ dielectron branching ratio [40]. Table 3 summarises the measured cross sections per invariant mass interval.

The measured dielectron cross sections at midrapidity are in very good agreement with the STARLIGHT predictions for coherent dielectron photoproduction (rightmost column of Table 3) [39]. Exclusive dilepton production in STARLIGHT is calculated combining the two equivalent (Weizsäcker–Williams) photon fluxes from each ion with the Breit–Wheeler formula for $\gamma\gamma \rightarrow l^+l^-$. The agreement between STARLIGHT and other leading order calculations [42] is good as long as the pair invariant mass is not too low. A recent calculation has found that higher order terms suppress the $e^+e^-$ cross section by 29% in the invariant mass range $140 < m_{e^+e^-} < 165$ MeV/c² [43]. A reduction of the same magnitude in the invariant mass range considered here, $2.0 < m_{e^+e^-} < 2.8$ GeV/c², would still be in agreement with our measurement.

The final $J/\psi + Xn$ cross section is compared to the theoretical predictions computed in references [12,14,25,27,39,44] in Fig. 4. The rapidity distributions for the coherent production of Strikman et al. [14] and Ivanov et al. [27] have been scaled down according to [12] to account for the reduction of the yield expected when requiring coincident forward neutron emission ($Xn$). The scaling has been applied as a function of rapidity with the integrated cross section being 55% of the original one.

The upper limit of the band covered by the Strikman et al. predictions corresponds to calculations in the impulse approximation (no shadowing), and the lower limit corresponds to calculations using the eikonal (Glauber) model with $\sigma(J/\psi + N) = 3$ mb. The bands for the calculations of Ivanov et al. corresponds to two different parameterisations of the dipole cross section [27]. The predictions by [14] and [27] for the coherent and incoherent photoproduction cross sections are drawn separately in Fig. 4(a) and summed up in Fig. 4(b). STARLIGHT [12,25,39] and Gonçalves–Machado [44] calculations only evaluate the coherent contribution.

As mentioned above, the measured pair $p_T$ distributions suggest coherent $J/\psi$ photoproduction $(\gamma + A \rightarrow J/\psi + X)$ and a possible additional incoherent $(\gamma + N \rightarrow J/\psi + X)$ contribution at higher $p_T$. To give an indicative estimate of the size of the incoherent contribution, we can assume that it corresponds to the counts in the $J/\psi$ mass window with $p_T > 0.1(0.05)$ GeV/c². This corresponds to about 4(6) counts, which amounts to a contribution of about 40(60)% of the total $J/\psi$ production, compatible with the theoretical calculations [14]. The limited data statistics prevents us from separating in a more quantitative way the two components. Note that although the acceptance correction for the $J/\psi$ was calculated using a Monte Carlo which includes only the coherent component, the obtained correction is also a reasonable approximation for the incoherent component, provided that quasi-elastic scattering on a single nucleon, $\gamma + N \rightarrow V + N$, gives the main contribution. The polarisation of the vector meson will then be the same as for coherent production, and the reduction in acceptance because of the different $p_T$ range will be of the order of $\sim 10$–20%. If the incoherent contribution to the total $J/\psi$ photoproduction was 40%, the coherent $J/\psi$ cross section would become $\sim 46$ μb.

Despite these uncertainties, the final $J/\psi$ cross section is in good agreement, within the (still large) statistical errors, with the theoretical values computed in [12,14,25,27,39,44] as shown in Fig. 4. The current uncertainties unfortunately preclude any more detailed conclusion at this point regarding the two crucial ingredients of the models (nuclear gluon shadowing and $J/\psi$ nuclear absorption cross section). The statistical uncertainties can be improved with significantly higher Au + Au luminosities and a concurrent measurement of the $J/\psi$ in the dimuon decay channel in the more forward acceptances covered by the PHENIX muon spectrometers.

Finally, one can attempt to compare the obtained photonuclear $J/\psi$ cross sections to those from e–e collisions at HERA by dividing the measured differential cross section ($d\sigma/dy$) by the (theoretical) equivalent photon spectrum ($dN_{\gamma}/dy$). At midrapidity: $\sigma_{pA \rightarrow J/\psi} = \frac{1}{\sigma_{AA \rightarrow J/\psi}} \frac{d\sigma_{pA \rightarrow J/\psi}}{dy} / \frac{dN_{\gamma}}{dy}$, with $2dN_{\gamma}/dy = 6.7 \pm 1.0$ GeV (10.5) for the coherent (incoherent) spectrum at a photon–nucleon center-of-mass energy of $(W_{\gamma}) = 24$ GeV [12]. Assuming, for the sake of simplicity, a 50–50% contribution from coherent and in-
coherent interactions in our total ultra-peripheral $J/\psi$ sample, the extracted photonuclear cross sections are: $\sigma(J/\psi + p \to J/\psi + n) = 30.5 \pm 2.7$ nb at $W_{J/\psi} = 24$ GeV. Therefore, the ratios $\sigma(J/\psi + Au \to J/\psi)/\sigma(J/\psi + p \to J/\psi) = 186 \pm 88$, $118 \pm 54$ for the coherent and incoherent components (statistical and systematic errors assumed independent and added in quadrature) are consistent with a scaling of the photonuclear cross section with the number of nucleons in gold ($A = 179$): $\frac{\sigma(J/\psi + Au \to J/\psi)}{\sigma(J/\psi + p \to J/\psi)} = A^0 \sigma(J/\psi + p \to J/\psi)$ with $\alpha_{coh} = 1.01 \pm 0.07$, and $\alpha_{incoh} = 0.92 \pm 0.08$, respectively.  

5. Summary and Conclusions

We have presented the first exclusive photoproduction of $J/\psi \to e^+e^-$ and high-mass $e^+e^-$ pairs ever measured in nucleus-nucleus (as well as hadron–hadron) interactions. The measurement has been carried out by the PHENIX experiment in ultra-peripheral Au + Au interactions at $\sqrt{s_{NN}} = 200$ GeV tagged by forward (ZDC) neutron detection from the (single or double) Au dissociation. Clear signals of $J/\psi$ and high mass dielectron continuum have been found in the data. We have observed $28 e^+e^-$ pairs in $m_{e^+e^-} \in [2.0, 6.0]$ GeV/c$^2$ with zero like-sign background. Their $p_T$ spectrum is peaked at low $p_T \approx 90$ MeV/c as expected for coherent photoproduction with a realistic Au nuclear form factor.

The measured number of continuum $e^+e^-$ events in the PHENIX acceptance for $m_{e^+e^-} \in [2.0, 2.8]$ GeV/c$^2$ is: $N(e^+e^-) = 13.7 \pm 3.7$(stat) $\pm 1.0$(syst). After correcting for acceptance and efficiency losses and normalising by the measured luminosity, we obtain a cross section of $d^2\sigma/dm_{e^+e^-} dy (e^+e^- + Xn)|_{y=0} = 86 \pm 23$(stat) $\pm 16$(syst) $\mu$b/(GeV/c$^2$), which is in good agreement with theoretical expectations for coherent exclusive dielectron production in photon–photon interactions.

The measured invariant mass distribution has a clear peak at the $J/\psi$ mass with an experimental width in good agreement with a full GEANT-based simulation for UPC production and reconstruction in the PHENIX detector. The measured number of $J/\psi$ mesons in the PHENIX acceptance is: $N(J/\psi) = 9.9 \pm 4.1$(stat) $\pm 1.0$(syst). The higher $p_T$ distribution suggests an additional incoherent contribution to $J/\psi$ photoproduction in accordance with predictions [14], but statistical limitations prevent a more quantitative estimate. After correcting for acceptance and efficiency losses and normalising by the measured luminosity, the total $J/\psi$ photoproduction cross section is $d\sigma/dy (J/\psi + Xn)|_{y=0} = 76 \pm 31$(stat) $\pm 15$(syst) $\mu$b, which is consistent (within uncertainties) with theoretical expectations. The low background in the present data sample shows that future higher luminosity runs with reduced experimental uncertainties of the measured cross sections will provide more quantitative information on the nuclear gluon distribution and $J/\psi$ absorption in cold nuclear matter at RHIC energies.

Acknowledgements

We thank the staff of the Collider-Accelerator and Physics Departments at BNL for their vital contributions.
