Summary
Eighty-eight fall born Angus heifers were used in a grazing study to evaluate supplementation of two levels of distillers dried grains with solubles (DDGS) supplemented on Southern Iowa pastures. The levels of supplementation were none (CONT), .5% of body weight (MED) and 1.1% of body weight (HIGH). Stocking rates were increased 22% and 44% for the MED and HIGH treatments compared to controls. Daily gains were 1.13, 1.30 and 1.47 lb. per day for CONT, MED and HIGH treatments. It appeared that cattle fed the HIGH level of supplementation had reduced pasture consumption, whereas MED levels did not. At current costs the HIGH level was more effective than MED at lowering cost per lb. of gain. Supplementation of DDGS improved cattle performance, but levels above .5% of body weight were necessary to substitute for pasture in this study.

Introduction
The rapid growth of the ethanol industry in the upper Midwest is well documented. This growth affects the Iowa cattle industry on several levels. Increased demand for corn puts pressure on feed and pasture costs and availability. However, increased production of distiller’s grains wet with solubles (DDGS) may provide an economical supplement to provide nutrients and stretch pasture supplies. DDGS have many benefits for forage based beef production. Relatively high levels of undegraded protein, can be needed early in the grazing season. Low levels of starch and high levels of phosphorous complement forage based systems. Convenient and cost effective systems of feed delivery may limit the successful application of supplementation programs incorporating DDGS. Also lower levels of supplements may simply stimulate feed intake rather than substitute for forage intake. This study was designed to evaluate two levels of DDGS supplementation with grazing heifers under Southern Iowa grazing conditions.

Materials and Methods
Eighty-eight fall born Angus heifers were blocked by sire and weight and randomly allotted to eight pastures and three supplement treatments. The three treatments were a non-supplemented control (CONT), medium level of supplementation (MED) and a high (HIGH) level of supplementation. These supplementation levels represented approximately .5 (MED) and 1.1 (HIGH) percent of the heifers body weight as distillers dried grains with solubles (DDGS). The eight pasture groups consisted of 16 paddocks ranging from 3.09 to 3.36 acres. Twelve of the paddocks consisted primarily of mixed cool season grasses. The remaining four paddocks contained a mixture of cool and warm-season grasses. A two pasture rotation was used for each replication. Two replications of the cool season pastures were assigned to each of the three supplement treatments. The pastures containing the warm season grasses were assigned to the MED treatment. Stocking rate differed by treatment. For each replication 9, 11 or 13 cattle were assigned to CONT, MED and HIGH levels, respectively.

The heifers were weighed, condition scored, and assigned to treatments on May 10, 2007. On July 6, they were re-weighed, condition scored, poured with Dectomax (doramectin, Pfizer) and tagged with organophosphate ear tags for fly control (Dominator, Schering). Final weights and condition scores were collected on September 27. Initial and final weights were taken with cattle off water and pasture 14 hours. Total grazing days were 136. All cattle were given access to a free choice mineral containing 12% Ca, 8% P, 10% salt, 2500 ppm Mn, 3000 ppm Cu, 23 ppm Ca, 30 ppm Sc, 5,000 ppm Zn, 300,000 IU/lb Vitamin A, 35,000 IU/lb. Vitamin D and 500 IU/lb. Vitamin E (as-fed). Supplemental rates were adjusted periodically for changes in cattle weights to target .5 and 1.1% of body weight for MED and HIGH treatments respectively. Pelleted distillers grain from an experimental pelleting process were available for use through the month of May. DDGS used June – Sept. was in the meal form and was fed in portable bunks. The analyses of the DDGS used in this study are shown in Table 1. Pasture sward heights were measured in ten locations when cattle were rotated in and out of each paddock. The data were analyzed using the GLM procedure of SAS. There was no pasture type effect and it was dropped from the model.

Results and Discussion

The weights, daily gains and condition scores of the heifers are shown in Table 2. Overall the weight gain of the heifers was less than expected. Weighing conditions may explain much of the relative differences in weight gain between the early and later part of the grazing season.

As might be expected, much of the response to supplementation came later in the grazing period. Overall, cattle on the high level of supplementation gained faster (P < .05) than controls. MED cattle gained faster than controls during the last 83 days. At the end of the experiment, supplemented cattle had higher condition scores, gaining .7 to .9 units during the grazing period, compared to controls.

Figure 1 shows the change in pasture sward heights by period. This clearly shows a reduction in pasture intake by the HIGH treatment compared to MED and CONT, especially early in the season. An attempt to calculate daily dry matter intake based on sward height reduction in grazed pastures and sward height growth in rested pastures yielded an estimate of 19.2, 18.5, and 10.8 for CONT, MED and HIGH, respectively. Considerable variation existed in sward height data and these values are quite high compared to expectations. The relative differences do appear to confirm that supplementing DDGS at .5% of the animal’s body weight may not reduce pasture intake. Supplementing at 1.1% of the animal’s body weight appeared to substitute for pasture.

Summarized in Table 3 are pasture productivity and pasture supplement costs. These costs are not intended to reflect total cost of production, only those costs that change given changes in the rate of supplementation. Given changes in stocking rates, (22 and 44% increase for MED and HIGH), and daily gain responses, gain per acre increased 81 and 607 lb. for MED and HIGH supplementation levels. Assuming pasture costs of $50 per acre and DDGS costs of $125 per ton, costs per lb. of gain actually increased with MED level of supplements, but decrease slightly with HIGH levels. This study supported the concept of using supplemental DDGS to increase pasture productivity, however feeding levels greater than 1% of body weight may be necessary to have a significant substitution effect on pasture consumption, and to lower costs of gain given current feed and pasture cost relationships.
