This Event is brought to you for free and open access by the Conferences and Symposia at Iowa State University Digital Repository. It has been accepted for inclusion in Proceedings of the Integrated Crop Management Conference by an authorized administrator of Iowa State University Digital Repository. For more information, please contact digirep@iastate.edu.
A major factor limiting soybean production in Iowa is parasitism by the soybean cyst nematode, *Heterodera glycines*. Soybean cyst nematode is now known to be present in 48 counties within Iowa. It is very likely that the nematode is present in many other counties as well, but the nonspecific nature of the above-ground symptoms of soybean cyst nematode damage makes early identification or diagnosis of infestations difficult.

The primary above-ground symptoms of soybean cyst nematode damage are chlorosis or yellowing and stunting of the soybean plants. These symptoms are not unique and often can be attributed to damage due to iron deficiency chlorosis, other nutrient deficiencies, drought stress, herbicide injury, compaction, or other plant diseases. In many instances, injury due to soybean cyst nematode has probably gone undetected because of these nondescript symptoms. In addition, the above-ground symptoms of soybean cyst nematode damage often do not occur consistently. Symptoms can range from nonexistent to severe depending on the age and vigor of the soybean plants, the population density of the nematode in the soil, the level of soil fertility and moisture, and other environmental conditions. One cannot rely upon above-ground symptoms for conclusive identification of a soybean cyst nematode infestation.

**Field Identification**

The only unique symptom of an infestation of soybean cyst nematode is the appearance of adult females and cysts of the nematode on the soybean roots. Adult females and cysts appear as tiny lemon-shaped objects which vary in color from cream to yellow to tan to brown, depending on the age of the nematode. They are large enough to be seen with the unaided eye but observation with a magnifying glass is usually easier. The cysts and adult females are about the size of a pinhead, considerably smaller than the nitrogen-fixing nodules on the roots. Roots must be carefully removed from the soil in the field, otherwise the cysts may become dislodged. Observation of these structures on the roots of soybean plants is the ONLY conclusive way to diagnose infestations of soybean cyst nematode in the field.

If soybean yields in a particular field have steadily decreased for no apparent reason or if cysts and adult soybean
cyst nematode females are observed directly on soybean roots in the field, a soil analysis is warranted.

Soil Sampling

Soil samples generally are taken to determine if soybean cyst nematode is present in the field or to determine the extent (population density) of an infestation in a field known to have the nematode. This is known as sampling for diagnostic and predictive purposes, respectively. Diagnostic soil sampling can be done at any time of the year but is usually performed when the soybean crop is in the field and the plants are showing above-ground symptoms. When sampling for diagnostic purposes, one should take separate samples from the problem area and from a nearby area which doesn't appear to be affected. Predictive soil sampling is performed in an attempt to gain information on the severity of a soybean cyst nematode infestation for use in making management decisions for the upcoming growing season. Predictive soil sampling is usually done in the fall, after the crops have been harvested. Individuals should sample fields that are going to be used for soybeans in the upcoming growing season and are suspected or confirmed to be infested with soybean cyst nematode. Information gained from predictive soil sampling in the spring would be more accurate, but there would not be enough time to implement management strategies based on the results of the samples. Following are guidelines that should be followed when taking predictive or diagnostic soil samples for soybean cyst nematode:

1. For predictive soil samples, limit the area sampled to no more than 10 acres. If a larger field is to be sampled, divide the field into 10 acre parcels and collect separate samples from each parcel. The fewer the number of acres represented in each sample, the more accurate and representative the results will be.

2. Use a 1-inch-diameter soil probe, if available, or a shovel to collect the soil. At 10 to 20 different places within the sampling area, collect a soil core or 1/4 cup of soil with a shovel. Soil should be collected at a depth of 6 to 8 inches, ideally from near the base of the plants if they are still present. All of the soil representing a single area should be placed in a bucket and mixed very thoroughly. From the well-mixed soil, remove approximately one pint to send in for processing.

3. If sampling for diagnostic purposes, soil should be collected from near plants showing the most severe symptoms as well as from near some that are not as severely affected. If sampling for predictive purposes, collect the soil in a systematic, zig-zag pattern within the area (Figure 1).
4. The soils to be tested should be placed in plastic or wax-coated paper bags to prevent drying and should be kept cool. Avoid storing the samples in the sun and ship the samples as soon as possible. Several facilities throughout the state and region will analyze soil samples for soybean cyst nematode. Soil samples can be sent to Iowa State University for soybean cyst nematode analysis. Samples should be sent to the Plant Nematologist, 321 Bessey Hall, Department of Plant Pathology, Iowa State University, Ames, IA 50011. Please include the following information on Form PD-32 for each sample sent to Iowa State University:

a. Name, address, and telephone number of grower and collector.
b. County and town nearest to where the sample was collected.
c. Estimated acreage that the sample represents.
d. Cropping history of the area sampled.
e. Current crop in the area sampled.

Figure 1. Sampling pattern for a 40 acre field. Asterisks represent subsampling points. Four separate samples should be taken from a 40 acre field.
Extraction Techniques

Following is an outline of the techniques used by the Iowa State University Cooperative Extension Service for determination of soybean cyst nematode population densities from soil samples. The procedure has three stages: extraction of the cysts from the soil, crushing of the cysts to release the eggs, and microscopic observation of the suspension of released eggs for enumeration.

Extraction of cysts from soil:

The technique used to recover the cysts of soybean cyst nematode from soil is a combination of wet-sieving and decanting. It is a modification of a mycological technique used to recover large spores of soil-inhabiting fungi (Gerdemann, 1955) and is based on the fact that the size range for soybean cyst nematode cysts is 470 - 790 µm by 210 - 580 µm. The procedure is as follows:

1. Obtain a well mixed 100 cc soil sample.
2. Fill a bucket with 2 quarts of water.
3. Pour the soil into the water, break any clumps with your fingers, and mix the soil suspension well for 15 seconds.
4. Let the suspension settle for 15 seconds.
5. Pour the soil suspension through a brass, 8-inch-diameter #20 850 µm pore) sieve nested over a #60 (250 µm pore) sieve. Any sediments that settle out in the bottom of the bucket should be discarded.
6. Rinse with water the debris caught on the top sieve then discard its contents. Carefully wash the cysts and accompanying sediments trapped on the #60 sieve into a clean, properly labeled beaker OR directly into a 100 ml polypropylene grinding tube using as little water as possible.

Extraction of eggs from the cysts:

The result of the above technique is a suspension of SCN cysts along with organic debris and sediments similar in size to the cysts. These cysts could be counted without much trouble using a simple dissecting microscope. In fact, some laboratories in Iowa that analyze soil for soybean cyst nematode report results in the form of cyst per 100 cc of soil. It is the opinion of many researchers, including those at Iowa State University, that the number of eggs contained within each cyst varies too much for cyst counts to be used as a reliable measure of the soybean cyst nematode population density. Therefore, Iowa State University does not provide cyst counts of soybean cyst
nematode. Instead, eggs are extracted from the cysts and results are reported in the form of eggs per 100 cc of soil.

Eggs of soybean cyst nematode average 47 μm by 100 μm.

The procedure used at Iowa State University to crush cysts to release and recover the eggs is as follows:

1. Wash the cyst suspension from the beaker into a 100 ml polypropylene grinding tube. Do not fill the tube more than half full.

2. Grind the cysts carefully between the inside surface of the tube and the 1-mm-deep grooves in a stainless steel pestle attached to a Talboys Model 101 motorized laboratory stirrer. Grind the cysts for exactly 60 seconds at 3,500 RPM (Boerma and Hussey, 1984). Rinse the pestle thoroughly with a wash bottle when finished grinding.

Alternatively, cysts may be crushed in a blender for 60 seconds at medium speed, provided a small canister is used atop the blender. The blender canister should hold no more than 500 ml or so for blending to be effective in rupturing the cysts.

3. After grinding or rupturing the cysts, pour the suspension in the tube or blender canister through a stainless steel, 3-inch-diameter #200 (75 μm pore) sieve nested over a #500 (25 μm pore) sieve. Rinse the tube or canister several times with tap water, each time pouring the contents through the sieves. Carefully rinse with water the sediments caught on the #200 sieve, then discard. Finally, carefully wash the sediments and eggs caught on the #500 sieve into a clean beaker with as little water as possible.

4. Place 4 to 5 drops of egg stain into each beaker of egg suspension. Egg stain consists of 3.5 g acid fuchsin dissolved in a solution of 250 ml acetic acid and 750 ml water (Byrd et al., 1983).

5. Heat beakers containing the eggs and stain in the microwave oven on full power until the suspension begins to boil. Several beakers of eggs can be microwaved at one time.

Counting the eggs:

After the egg suspensions cool, eggs can be observed using a rectangular counting dish and a dissecting microscope. Counting dishes are made by scratching four narrow lanes in the bottom half of clear plastic rectangular hinged boxes using a sharp dissecting needle. The total area of the four lanes should equal half of the total area of the bottom of the hinged box.
The volume of the egg suspension in the beaker should be brought up to 50 to 100 ml with tap water. Pipette a known volume of well-mixed egg suspension (2 to 5 ml) into the rectangular counting dish, count the number of eggs in the four lanes, and multiply by two to get the total number of eggs per volume originally added to the dish. The surface of the egg suspension in the counting dish may be sprayed with 95% ethanol to break surface tension and facilitate sinking of the eggs.

**Literature Cited**

**Sources of Materials and Equipment**

I. Soil sampling probes:

Various types of 1-inch-diameter soil sampling probes can be ordered from the following companies:

Ben Meadows Company, 3589 Broad Street. P.O. Box 80549, Atlanta, GA 30366

Clements Associates, Inc., R.R.#1 Box 186, Newton, IA 50208 (515) 792-8285

Forestry Suppliers, Inc., 205 W. Rankin Street, P.O. Box 8397, Jackson, MS 39284-8397 (601) 354-3565

Oakfield Apparatus Inc., P.O. Box 65, Oakfield, WI 53065 (414) 583-4114

II. Sieves:

Sieves may be purchased through either of the following distributors:

Fisher Scientific, 1600 W. Glenlake Avenue, Itasca, IL 60143 (800) 223-9114

VWR Scientific, P.O. Box 66929, O'Hare AMF, Chicago, IL 60666 (800) 932-5000

Note: The brass, 8-inch-diameter #20 and #60 sieves are generally in stock but the stainless steel, 3-inch-diameter #200

164
and #500 sieves will probably have to be special-ordered through the distributor.

III. Polypropylene 100 ml grinding tubes:

Nalgene round lip, polypropylene, 100 ml centrifuge tubes can be ordered through Fisher Scientific (cat. # 05-562-10C, $31.80/pkg. of 10).

IV. Stainless steel pestle with 1mm ridges:

The stainless steel pestle used to grind the cysts is custom manufactured for our purposes by the Iowa State University Engineering Research Institute (ERI) Machine Shop. The ERI Machine Shop will make this item for individuals outside of the university as well. Contact the ERI Machine Shop, 124 ERI Building, Iowa State University, Ames, IA 50011 for further details. Remember to mention that the pestle is to be identical to those previously made at the facility for Dr. Gregory Tylka in the Department of Plant Pathology.

V. Motorized stirrer for stainless steel pestle:

The motorized laboratory stirrer used with the stainless steel pestle is a Talboys Model 101 stirrer. This stirrer can be purchased through VWR Scientific or directly through Talboys Engineering Corporation, South Montrose, PA 18843.

VI. Rectangular counting dishes:

Rectangular counting dishes can be made from clear plastic boxes obtained from Althor Products, 496 Danbury Road, Wilton, CT 06897. Order catalog # H-12, 2 7/8" x 1 3/16" x 1" clear polystyrene hinged boxes, $0.35 each or $29.00 per 100 (makes 200 dishes).
