An inverse Ruddlesden-Popper nitride $\text{Ca}_7(\text{Li}_{1-x}\text{Fe}_x)\text{Te}_2\text{N}_2$ grown from Ca flux

Abstract
Nitridoferrates containing monovalent iron ions are a class of materials of recent interest as potentially novel magnetic materials. Aiming at the exploration of nitridoferrates of calcium, we report the single crystal growth from Ca flux and crystal structure of the first member ($n = 2$) of a series of inverse Ruddlesden-Popper nitrides with a general formula of $\text{An}^{-1}\text{A'}_2\text{B}_n\text{X}_{3n+1}$, where $\text{A} = \text{Li}/\text{Fe}$, $\text{A'} = \text{Te}$, $\text{B} = \text{N}$, and $\text{X} = \text{Ca}$. Single crystal X-ray diffraction analyses indicate the crystal with a composition of $\text{Ca}_7(\text{Li}_{0.32(1)}\text{Fe}_{0.68(1)})\text{Te}_2\text{N}_2$ and the tetragonal space group $I4/mmm$ ($a = 4.7884(1) \, \text{Å}, c = 25.3723(4) \, \text{Å}, Z = 2$). The structure features alternately stacking NaCl-type $\text{A'}\text{X}$ slabs and the perovskite-type $\text{ABX}_3$ slabs along the $c$ axis. The Li/Fe atoms are located in cuboctahedral cavities surrounded by eight Ca6N octahedra in the $\text{ABX}_3$ slab. This work demonstrates the viability of the Ca-rich flux as a suitable solvent for the exploration of new complex nitrides with interesting crystal structure and properties.

ABSTRACT

Nitridoferrates containing monovalent iron ions are a class of materials of recent interest as potentially novel magnetic materials. Aiming at the exploration of nitridoferrates of calcium, we report the single crystal growth from Ca flux and crystal structure of the first member ($n = 2$) of a series of inverse Ruddlesden-Popper nitrides with a general formula of $A_{n-1}A'_2B_nX_{3n+1}$, where $A = \text{Li}/\text{Fe}$, $A' = \text{Te}$, $B = \text{N}$, and $X = \text{Ca}$. Single crystal X-ray diffraction analyses indicate the crystal with a composition of $\text{Ca}_7(\text{Li}_{0.32(1)}\text{Fe}_{0.68(1)})\text{Te}_2\text{N}_2$ and the tetragonal space group $I4/mmm$ ($a =$
4.7884(1) Å, \( c = 25.3723(4) \) Å, \( Z = 2 \)). The structure features alternately stacking NaCl-type A'X slabs and the perovskite-type \( \text{ABX}_3 \) slabs along the \( c \) axis. The \( \text{Li}/\text{Fe} \) atoms are located in cuboctahedral cavities surrounded by eight \( \text{Ca}_6\text{N} \) octahedra in the \( \text{ABX}_3 \) slab. This work demonstrates the viability of the Ca-rich flux as a suitable solvent for the exploration of new complex nitrides with interesting crystal structure and properties.

Nitrides; crystal growth; flux; crystal structure; Ruddlesden-Popper phase

### 1. Introduction

Binary nitride materials have attracted strong interest in both science and technology for their properties over the past decades. GaN and its III-V solid solutions are semiconductors widely used for the light emitting diode, laser diode, photodetector, and sensor application [1-5]. NbN, ZrN, and HfN are well known superconductors with relatively high superconducting transition temperatures for conventional superconductors [6-8]. Hexagonal BN is a good lubricant over a wide temperature range and a two-dimensional (2D) material offering a remarkable opportunity for advanced 2D devices [9,10]. Cubic BN and wurtzite BN are reported to have a hardness comparable to diamond [11,12].

More recently, interest in complex nitrides, like ternary and quaternary nitrides, has increased due to their specific properties [13]. Among complex nitrides, nitridoferrates of alkaline and alkaline earth metals, containing monovalent iron have attracted specific attention. Up to now, several nitridoferrates featuring one-dimensional (1D) \( \text{N}-(\text{Li}/\text{Fe})-\text{N} \) chains, such as \( \text{Li}_2[(\text{Li}_{1-x}\text{Fe}_x)\text{N}] \) [14,15], \( \text{CaLi}_2[(\text{Li}_{1-x}\text{Fe}_x)\text{N}]_2 \) [16], \( \text{SrLi}_2[(\text{Li}_{1-x}\text{Fe}_x)\text{N}]_2 \) [16], \( \text{Ca}_2\{(\text{Li}_{1-x}\text{Fe}_x)\text{N}_2\} \) [17], and \( \text{Li}_2\text{Sr}[(\text{Li}_{1-x}\text{Fe}_x)\text{N}]_2 \) [18] have been reported. \( \text{Li}_2[(\text{Li}_{1-x}\text{Fe}_x)\text{N}] \) [15] and \( \text{Li}_2\text{Sr}[(\text{Li}_{1-x}\text{Fe}_x)\text{N}]_2 \) [18] have
remarkable magnetic anisotropy and coercivity, which are desired for functional magnetic materials. Unlike the infinite N-(Li/Fe)-N chains, discrete N-(Li/Fe)-N linear blocks surrounded by Ca ion were discovered in the newly synthesized Ca$_6$(Li$_{1-x}$Fe$_x$)Te$_2$N$_3$ [19,20], which demonstrates the variety of possible coordination environments for the (Li/Fe)-N units.

Compared with their oxide counterparts, the growth and study of complex nitrides are difficult. Elemental nitrogen usually forms the diatomic molecule N$_2$ which has a strong covalent triple bond. The transition from atomic N to a N$^{3-}$ anion needs to overcome a high energy barrier. Many of the nitrides are metastable phases and easily decompose. On one hand, these issues contribute to the challenge of synthesising nitride materials. On the other hand, this situation offers a vast unexplored territory and creates excellent opportunities to discover new nitride materials with interesting crystal structures and properties by developing suitable synthetic methods to overcome these obstacles.

Tremendous efforts have been devoted to preparing nitrides by solid-state reaction [21], ammonolysis [22], solid-state metathesis [23,24], vapour deposition [25], carbothermal reduction [26], reactive sputtering [27], precursor decomposition [28], solvothermal process [29], and solution growth [30,31]. The solution growth method utilises low melting point metals, such as alkaline metals or alkaline earth metals, as flux, dissolves reactants and facilitates reactions by attenuating the energy barrier for breaking the N-N bonding. Na, Li, and Ca flux have been successfully used to grow GaN single crystal [32-37], as well as other nitrides [31]. As such, the viability of alkaline metal and alkaline earth metal fluxes should definitely not be limited to the single crystal growth of binary nitrides.

Nitrogen is highly soluble in Ca [38], which also has a moderately high melting point 842 °C. The eutectic point of Ca-Ca$_3$N$_2$ is determined to be at 1.94 at.% N and 814 °C [39]. As such, Ca-rich
flux is postulated to be a suitable solvent for the exploration of complex nitrides of calcium. Here we report the discovery of an inversed Ruddlesden-Popper (RP) nitride Ca$_7$(Li$_{1-x}$Fe$_x$)Te$_2$N$_2$ with $x = 0.68(1)$ grown by Ca flux. It crystallises in the tetragonal space group $I4/mmm$ and contains a Li/Fe mixed site inside the cuboctahedral cavities defined by Ca$_6$N octahedra.

2. Experimental section

Ca$_7$(Li$_{1-x}$Fe$_x$)Te$_2$N$_2$ single crystals were grown by the solution growth method out of Ca-rich flux. Distilled Ca pieces (> 99.9%, Material Preparation Center (MPC), Ames Laboratory), lithium foil (99.9%, Alfa Aesar), tellurium (99.999%, Alfa Aesar), iron (99.99%, Alfa Aesar), and Ca$_3$N$_2$ (99%, Alfa Aesar) were weighed in the molar ratios of Ca:Li:Te:Fe:Ca$_3$N$_2$ = 7:1:1:0.1:1 and put inside a three-cap Ta crucible in an argon-filled glovebox [31]. The Ta crucible was sealed by arc welding under argon and loaded into an amorphous silica ampoule, which was sealed under roughly 0.2 atmosphere argon to prevent the oxidisation of Ta during the growth process. The growth ampoule was heated over 3 hours to 450 °C, held for 3 hours to melt tellurium and to react the elements, then heated over 12 hours to 1100 °C, held at this temperature for 4 hours, slowly cooled to 875 °C over 74 hours, and finally the assembly was decanted in a centrifuge to separate crystals from the remaining liquid. The Ca$_7$(Li$_{1-x}$Fe$_x$)Te$_2$N$_2$ crystals grow as rods with diameters ranging from several tens microns to millimeters and of lengths up to 7 mm, see Fig. 1. Single crystals of Ca$_7$(Li$_{1-x}$Fe$_x$)Te$_2$N$_2$ are very air sensitive and degrade within a few minutes in air. Besides Ca$_7$(Li$_{1-x}$Fe$_x$)Te$_2$N$_2$, CaTe was found as a byproduct.

Small Ca$_7$(Li$_{1-x}$Fe$_x$)Te$_2$N$_2$ pieces were selected under a microscope in a nitrogen-filled glovebox and sealed in quartz capillaries. Single-crystal X-ray diffraction data were collected at room temperature using a Bruker APEX II diffractometer equipped with a CCD area detector with Mo
Kα radiation. Refinements of the diffraction data were performed using the SHELXTL package [40].

The chemical compositions of Ca7(Li1−xFex)Te2N2 single crystals were determined using a Bruker Aurora Elite Inductively Coupled Plasma Mass Spectrometer (ICP–MS) without collision gas. Samples were dissolved in 1% nitric acid, 1% hydrochloric acid solutions. The total mass of solute ranged from 0.6 mg to 3.4 mg, with a final sample solution concentration of 500 ppb. The isotopes analyzed were 7Li+, 42Ca+, 43Ca+, 44Ca+, 56Fe+, 57Fe+, and 125Te+. External calibration curves of net signal vs. concentration were created using standard concentrations of 20, 200, and 2000 ppb. The molar ratios of (Li+Fe)/Ca and Li/Fe were determined as 0.147 and 0.471, respectively. The [(standard deviation/mean result) * 100] (%RSD) of the solution concentration in ppb for Li, Fe, and Ca are 1.25, 0.08, and 0.79, respectively.

The isothermal magnetization of Ca7(Li1−xFex)Te2N2 was measured as a function of magnetic fields (up to ± 5 T) that were applied parallel and perpendicular to the rod at 5 K and 300 K. No apparent magnetic anisotropy between the two measured directions was observed. The saturated magnetic moments for both directions are about 0.02 μB/Fe, likely a result of impurity. We tried to measure the resistance of Ca7(Li1−xFex)Te2N2 crystals by multimeter or making contacts using silver paint in the nitrogen-filled glovebox. In both cases, the resistance (sample and/or contacts) was too large to be measured.

3. Results and discussion

The crystal structure was determined by a direct method in the tetragonal structure with space group I4/mmm, in which the five independent metal sites were identified. Atomic assignments were made on the basis of peak intensities and bond distances to neighboring atoms. Subsequent difference Fourier map yield the N site. The final refinement with anisotropic displacement
parameters yielded a formula of \( \text{Ca}_7(\text{Li}_{0.32(1)}\text{Fe}_{0.68(1)})\text{Te}_2\text{N}_2 \). This proportion is consistent with the chemical composition determined by ICP–MS, which yielded a molar ratio of \((\text{Li} + \text{Fe})/\text{Ca}\sim0.147\). Representative crystallographic data of the structural refinement are listed in Tables 1, 2, and 3. As shown in Fig. 2(a), the structure of \( \text{Ca}_7(\text{Li}_{0.32(1)}\text{Fe}_{0.68(1)})\text{Te}_2\text{N}_2 \) manifest nitrogen centered \( \text{Ca}_6 \) octahedra, defined by four \( \text{Ca}_1 \) atoms on the waist, and one \( \text{Ca}_2 \) atom capping on the top and one \( \text{Ca}_3 \) capping on the bottom. The \( \text{Ca}_6\text{N} \) octahedra are slightly distorted along \( c \)-axis, as indicated by the bond distance of \( d_{N-\text{Ca}2} = 2.325(3) \text{ Å} \) and \( d_{N-\text{Ca}3} = 2.495(3) \text{ Å} \) (see Table 3). These \( \text{Ca-N} \) distances of 2.325(3) Å, 2.4055(3) Å (\( d_{N-\text{Ca}1} \)), and 2.495(3) Å are within the range of reported \( \text{Ca-N} \) bond lengths for \( \text{Ca}_3\text{N}_2 \) (2.46 Å), \( \text{Ca}_{11}\text{N}_8 \) (2.308-2.900 Å), and \( \text{Ca}_2\text{N} \) (2.4426(4) Å) \[41-43\]. All \( \text{Ca}_1 \) and \( \text{Ca}_3 \) atoms are shared by neighboring octahedra to form 2D perovskite-type \( \text{ABX}_3 \) slabs, which are stacked along \( c \)-axis and separated by the more electronegative Te atoms. The \( \text{Li}/\text{Fe} \) atoms are located at the centers of cuboctahedral cavities in the perovskite layers, shown in Fig. 3(a). The \( \text{(Li}/\text{Fe})-\text{Ca} \) distances are 3.2930(4)-3.3859(1) Å, within the range of \( \text{Ca-Li} \) and \( \text{Ce-Fe} \) distances commonly observed in intermetallics, e.g., \( d_{\text{Ca-Li}} = 3.672 \text{ Å} \) in Laves phase \( \text{CaLi}_2 \) \[44\] and \( d_{\text{Ca-Fe}} = 3.219(1) \text{ Å} \) in \( \text{CaFe}_2\text{Si}_2 \) \[45\]. The Te atoms in \( \text{Ca}_7(\text{Li}_{0.32(1)}\text{Fe}_{0.68(1)})\text{Te}_2\text{N}_2 \) are located between neighboring perovskites slabs; each has nine neighboring \( \text{Ca} \) atoms in its first coordinating sphere, shown in Figure 3(b).

Simply judging from the formula of \( \text{Ca}_7(\text{Li}_{0.32(1)}\text{Fe}_{0.68(1)})\text{Te}_2\text{N}_2 \), the title 7-1-2-2 phase seems to have a certain underpinned relationship with \( \text{Ca}_6\text{Li}_{0.48}\text{Fe}_{0.52}\text{Te}_2\text{N}_3 \) \[19\], or in short, 6-1-2-3 phase. However, their differences are remarkable: (1) there are two sets of \( \text{N} \) atoms in the 6-1-2-3 structure, one with octahedral coordination of six calcium atoms and the other with five calcium and one \( \text{Li}/\text{Fe} \) atoms, as shown in Fig. 2(b). Noteworthy is that \( \text{Fe} \) in the 6-1-2-3 phase can be considered as a cationic atom with a rare formal charge of +1 \( (d^6s^1 \text{ configuration}) \), as confirmed
by susceptibility data and theory calculations [19]. Yet the same is not true for the 7-1-2-2 phase, which in fact is a metallic phase. (2) The Li/Fe-Li/Fe separation in the 6-1-2-3 phase is $c/2 = 3.36$ Å [19]. However, each Li/Fe in the 6-1-2-3 structure has direct bonding interaction with two electronegative N atoms with a distance of 1.86 Å. This could yield Fe-N-Fe super-exchange interactions as indicated by susceptibility data [19]. In contrast, Li/Fe in perovskite-type layer of the 7-1-2-2 phase is surrounded by 12 Ca atoms and no direct Li/Fe-N bonding exists as the separation is 4.7884(1) Å. Therefore, this material likely does not show strong magnetic response because of an expected electron delocalisation in the Ca$_3$N(Li/Fe) perovskite slab with intermetallic nature. In other words, the local region in the perovskite slabs is in fact dominated by homoatomic Ca-Ca and heteroatomic Ca-Li/Fe metallic bonding interactions. Although susceptibility and resistance data for Ca$_7$(Li$_{0.32(1)}$Fe$_{0.68(1)}$)Te$_2$N$_2$ are not available, metallic luster is seen for the title crystals (cf. Figure 1).

In fact, the present 7-1-2-2 structure can be considered as the first member ($n = 2$) of an inverse RP phase, with a general formula of $A_{n-1}A'||2B_nX_{3n+1}$, here $A = Li/Fe$, $A' = Te$, $B = N$, and $X = Ca$. This type structure features alternately stacking NaCl-type $A'X$ slabs and the perovskite-type $ABX_3$ slabs along the long axis. With this formula in hand, a series of new phases in the same system could be designed and to be synthesized by stoichiometric solid-state reactions, e.g., Ca$_4$Te$_2$N ($n = 1$) and Ca$_{10}$(Li$_{1-\lambda}$Fe$_{\lambda}$)$_2$Te$_2$N$_3$ ($n = 3$).

4. Conclusions

A novel inverse RP nitride Ca$_7$(Li$_{1-\lambda}$Fe$_{\lambda}$)Te$_2$N$_2$ with $x = 0.68(1)$ was successfully grown from Ca flux. The single-crystal XRD indicates that it crystallizes in the tetragonal space group $I4/mmm$ and contains Li/Fe ions located in cuboctahedral cavities in the perovskite-type layers formed by
Ca₆N octahedra. This work demonstrates the viability of Ca flux to crystallize new complex nitride, and predicts the existence of a series of new inversed RP phases in the title system.
