Event-by-event fluctuations in mean p(T) and mean e(T) in root s(NN)=130 GeV Au+Au collisions

Abstract
Distributions of event-by-event fluctuations of the mean transverse momentum and mean transverse energy near mid-rapidity have been measured in Au+Au collisions at roots(NN)=130 GeV at the Relativistic Heavy-Ion Collider. By comparing the distributions to what is expected for statistically independent particle emission, the magnitude of nonstatistical fluctuations in mean transverse momentum is determined to be consistent with zero. Also, no significant nonrandom fluctuations in mean transverse energy are observed. By constructing a fluctuation model with two event classes that preserve the mean and variance of the semi-inclusive p(T) or e(T) spectra, we exclude a region of fluctuations in root s(NN)=130 GeV Au+Au collisions.

Event-by-event fluctuations in mean $p_T$ and mean $\epsilon_T$ in $\sqrt{s_{NN}}=130$ GeV Au+Au collisions

Distributions of event-by-event fluctuations of the mean transverse momentum and mean transverse energy near mid-rapidity have been measured in Au+Au collisions at $\sqrt{s_{NN}} = 130$ GeV at the Relativistic Heavy-Ion Collider. By comparing the distributions to what is expected for statistically independent particle emission, the magnitude of nonstatistical fluctuations in mean transverse momentum is determined to be consistent with zero. Also, no significant nonrandom fluctuations in mean transverse energy are observed. By constructing a fluctuation model with two event classes that preserve the mean and variance of the semi-inclusive $p_T$ or $\varepsilon_T$ spectra, we exclude a region of fluctuations in $\sqrt{s_{NN}} = 130$ GeV Au+Au collisions.

I. INTRODUCTION

Phase instabilities near the QCD phase transition can result in nonstatistical fluctuations that are detectable in final state observables [1]. These instabilities, which may occur due to random color fluctuations [2], critical behavior at the QCD tricritical point [3], or fluctuations from the decay of a Polyakov loop condensate [4], can result in a broadening of the transverse momentum or transverse energy distributions of particles produced for different classes of events. This phenomenon is expected to be detected experimentally by searching for deviations of the distributions of the event-by-event mean transverse momentum $M_{p_T}$ or mean transverse energy $M_{\varepsilon_T}$ of produced particles from the random distributions expected for statistically independent particle emission.

An event-by-event analysis of $M_{p_T}$ was previously performed for 158 A GeV/c Pb+Pb collisions at the CERN SPS by Experiment NA49 [5]. In that analysis, the $M_{p_T}$ distributions measured over the rapidity range $4 < y_p < 5.5$ and $p_T$ range 0.005 < $p_T$ < 1.5 GeV/c were found to be consistent with random fluctuations. NA49 also performed an event-by-event analysis of the $K/\pi$ ratio [6], showing only very small deviations from random fluctuations. With an increase of $\sqrt{s_{NN}}$ to 130 GeV in Relativistic Heavy-Ion Collider (RHIC) collisions, unprecedented energy densities have been observed [10]; hence conditions may be more favorable for a phase transition from hadronic matter to a quark-gluon...
plasma which may be indicated in nonrandom fluctuations. Presented here is an event-by-event analysis of $M_{p_T}$ fluctuations and the first measurement of $M_{e_T}$ fluctuations at mid-rapidity at the RHIC.

## II. ANALYSIS

The PHENIX Experiment [7] consists of four spectrometers designed to measure simultaneously hadrons, leptons, and photons produced in nucleus-nucleus, proton-nucleus, and proton-proton collisions at RHIC. The two central arm spectrometers, which are located within a focusing magnetic field, each covering ±0.35 in pseudorapidity and Δφ = 90° in azimuthal angle, are utilized in this analysis. The primary interaction trigger was defined using the Beam-Beam Counters (BBCs) [8] and Zero Degree Calorimeters (ZDCs) [9]. Events are selected with a requirement that the collision vertex along the beam axis has $|z| < 20$ cm as measured by both the BBCs and ZDCs. Event centrality is defined using correlations in the BBC and ZDC analog response as described in [10]. For the present analysis, the events are classified according to the 0–5 %, 0–10 %, 10–20 %, and 20–30 % most central events.

The drift chamber [11] is used in conjunction with the innermost pad chamber, called PC1, to measure the transverse momentum of charged particles traversing the PHENIX acceptance. A fiducial section of the drift chamber is chosen to minimize the effect of time-dependent variations in the performance of the detector during the data-taking period. The fiducial volume of the $M_{p_T}$ analysis spans an azimuthal range of Δφ = 58.5° and covers the pseudorapidity range $|η| < 0.35$. Reconstructed tracks [12] are required to contain a match to a hit in PC1 to ensure that the tracks are well reconstructed in three dimensions for reliable momentum determination.

The $M_{e_T}$ distribution is determined from clusters reconstructed in the two instrumented sectors of the lead-scintillator electromagnetic calorimeter [7,13,14]. The quantity $e_T$ is defined as the transverse energy per reconstructed calorimeter cluster as described in [14], which can include clusters that have been merged. The effects of cluster merging on the $M_{e_T}$ distribution are discussed later. The fiducial volume of the $M_{e_T}$ analysis spans an azimuthal range of Δφ = 45° and covers $|η| < 0.35$.

There are no acceptance or efficiency corrections applied to the semi-inclusive $p_T$ or $e_T$ distributions prior to the calculation of $M_{p_T}$ or $M_{e_T}$. Here, the term semi-inclusive refers to spectra in $p_T$ or $e_T$ summed over all events in a given centrality class. These corrections do not vary from event to event.

mixed events, which are events of multiplicity $m$, are considered independently of each other. The $M_{p_T}$ distributions are calculated using the formula

$$M_{p_T} = \left(\frac{1}{N_{\text{tracks}}}\right) \sum_{i=1}^{N_{\text{tracks}}} p_{T_i}$$

(2.1)

where $N_{\text{tracks}}$ is the number of tracks in the event that pass the cuts outlined above and lie within the $p_T$ range $0.2 < p_T < 1.5$ GeV/$c$. Similarly, the $M_{e_T}$ distributions are calculated using the formula

$$M_{e_T} = \left(\frac{1}{N_{\text{clus}}}\right) \sum_{i=1}^{N_{\text{clus}}} e_{T_i}$$

(2.2)

where $N_{\text{clus}}$ is the number of calorimeter clusters in the event that lie within the $e_T$ range $0.225 < e_T < 2.0$ GeV. An event is excluded from the analysis if $N_{\text{tracks}}$ or $N_{\text{clus}}$ is below a minimum value to ensure that there are a sufficient number of tracks or clusters to determine a mean and to exclude background events. This minimum value for the 0–5 %, 0–10 %, 10–20 %, and 20–30 % centrality classes, respectively, is 40, 30, 20, and 10 for the $M_{p_T}$ analysis and 30, 20, 10, and 10 for the $M_{e_T}$ analysis. Table I lists statistics pertaining to the data samples used to determine $M_{p_T}$, and Table II lists the statistics pertaining to the data samples used to determine $M_{e_T}$. The events used for the $M_{p_T}$ and $M_{e_T}$ analyses are considered independently of each other.

In order to compare the $M_{p_T}$ and $M_{e_T}$ distributions to what is expected for statistically independent particle emission, the baseline for the random distribution is defined by mixed events, which are events of multiplicity $m$ assembled using individual tracks or clusters taken from a collection of $m$ data events with one track or cluster taken from each data event. To obtain a precision comparison, it is important to match the number of tracks or clusters along with the mean of the semi-inclusive distribution of the mixed events to those of the data. Therefore, in both analyses, mixed events are constructed by predetermining the number of charged particle tracks or calorimeter clusters in the mixed event $N_{\text{mix}}$ by directly sampling the corresponding data $N_{\text{tracks}}$ or $N_{\text{clus}}$ distributions. Figure 1 shows a comparison of the $N_{\text{tracks}}$ distributions from the data and the normalized mixed event $N_{\text{mix}}$ distribution for the 0–10 % centrality class. Once $N_{\text{mix}}$ is determined, a mixed event is filled with $p_T$ or $e_T$ values from the data with the following criteria: (a) no two $p_T$ or $e_T$ values from the same data event are allowed to reside in the same mixed event, (b) only $p_T$ or $e_T$ values passing all cuts in the determination of $M_{p_T}$ or $M_{e_T}$ from the data events are placed in a mixed event, and (c) only data events from the same centrality class are used to construct a mixed event corresponding to that class. Once a mixed event is filled with $N_{\text{mix}}$ tracks or clusters, its $M_{p_T}$ or $M_{e_T}$ is calculated in the same manner as for the data events.

For both analyses, the data contain a fraction of tracks or clusters within close physical proximity that have merged into a single track or cluster. This fraction is estimated by embedding simulated single-particle events that are processed through a detailed simulation of the detector response into real data events, which are then reconstructed in the same manner as the data. For the 0–5 % centrality class, we estimate that 6% of the tracks and 5% of the clusters are affected.

For the $M_{p_T}$ analysis, tracks that are merged into a single reconstructed track typically have similar values of $p_T$. The result is a slightly lower value of $N_{\text{tracks}}$ which causes a slight broadening in the width of the $M_{p_T}$ distribution due to the reduced statistics per event. However, since the $N_{\text{tracks}}$...
data distribution is directly sampled during the construction of mixed events, the effect of merged tracks cancels for comparisons between the data and mixed events.

For the $M_{\varepsilon_T}$ analysis, the effect of merged clusters is complicated by the fact that a single cluster is reconstructed with an $\varepsilon_T$ corresponding to the sum of the two (or more) particles contributing to the cluster. To understand this effect on the mixed events, we note that the fraction of merged clusters within a data event increases with event multiplicity. Also, many of the data events with the lowest $M_{\varepsilon_T}$ coincide with the lowest multiplicity events since they contain few, if any, merged clusters that would yield a higher $M_{\varepsilon_T}$. When the merged clusters in the data events are randomly redistributed among the mixed events, low multiplicity mixed events can contain more merged clusters than the data events with the same multiplicity, resulting in a gross upward shift in $M_{\varepsilon_T}$ for those mixed events. This results in apparent excess non-random fluctuations at low $M_{\varepsilon_T}$. Conversely, high multiplicity mixed events can contain fewer merged clusters than the data events with the same multiplicity, resulting in a gross downward shift in $M_{\varepsilon_T}$ for those mixed events. However, since the mean is taken over more clusters in this case, the effective shift in $M_{\varepsilon_T}$ is reduced at high $M_{\varepsilon_T}$, and the apparent nonrandom fluctuations are much less pronounced. An estimate of the magnitude of this effect is presented later.

III. RESULTS

To compare directly the semi-inclusive $p_T$ distribution to the $M_{p_T}$ distribution assuming a statistically independent particle emission, the closed form prescription outlined in [15] is used. This prescription describes the semi-inclusive $p_T$ distribution using a Gamma distribution,

$$f(p_T) = f_1(p_T; p, b) = \frac{b}{\Gamma(p)} (bp_T)^{p-1} e^{-bp_T},$$  \hspace{1cm} (3.1)

where $p$ and $b$ are free parameters that are related to the mean and standard deviation of the semi-inclusive distribution as

$$p = \frac{\langle p_T \rangle^2}{\sigma_{p_T}^2}, \quad b = \frac{\langle p_T \rangle}{\sigma_{p_T}^2},$$  \hspace{1cm} (3.2)

where

$$\sigma_{p_T} = (\langle p_T^2 \rangle - \langle p_T \rangle^2)^{1/2}. \hspace{1cm} (3.3)$$

The reciprocal of $b$ is the inverse slope parameter of the $p_T$ distribution. With the track multiplicity distribution assumed to be a negative binomial distribution, $f_{NBD}(N_{\text{tracks}}; 1/k, \langle N_{\text{tracks}} \rangle)$, the $M_{p_T}$ distribution can be calculated using

$$g(p_T) = \sum_{N=N_{\text{min}}}^{N_{\text{max}}} f_{NBD}(N, 1/k, \langle N \rangle) f_1(p_T; Np, Nb),$$  \hspace{1cm} (3.4)

where the sum is over $N_{\text{tracks}}$ from $N_{\text{min}}$ to $N_{\text{max}}$, which are the limits of the multiplicity. The value of the negative binomial distribution parameter $k$ is given by

FIG. 3. The $M_{p_T}$ distributions for all centrality classes. The curves are the random baseline mixed event distributions.
Therefore, given $<p_T>$, $\sigma_{p_T}$, and $\langle N_{\text{tracks}} \rangle$ extracted from the semi-inclusive $p_T$ distribution, the expected random $M_{p_T}$ distribution can be calculated. Figure 2 shows the $M_{p_T}$ distribution for the 0–5 % centrality class. Overlaid on the data as a dotted curve is the result of the calculation. The agreement between the data distribution and the calculation illustrates the absence of large nonstatistical fluctuations in the data. The remainder of this paper will quantify the amount of non-

\[
\frac{1}{k} = \frac{\sigma_{p_T}^2}{\langle N_{\text{tracks}} \rangle^2} - \frac{1}{\langle N_{\text{tracks}} \rangle}.
\]

FIG. 4. The $M_{p_T}$ distributions for all centrality classes. The curves are the random baseline mixed event distributions. The source of differences in the data and mixed event distributions are addressed in the text.

FIG. 5. The residual distribution between the data and mixed event $M_{p_T}$ spectra as a function of $M_{p_T}$ in units of standard deviations for all centrality classes. The total $\chi^2$ and the number of degrees of freedom for the 0–5 %, 0–10 %, 10–20 %, and 20–30 % centrality classes are 89.0/37, 155.7/40, 163.3/47, and 218.4/61, respectively.
statistical fluctuations observed and place limits on the level of fluctuations that can be present in central Au+Au collisions at \( \sqrt{s_{NN}} = 130 \) GeV.

To quantify the magnitude of the deviation of fluctuations from the expectation of statistically independent particle emission, the magnitude of the fluctuation \( \omega_T \) in the transverse quantity \( M_T \), representing \( M_{p_T} \) or \( M_{e_T} \), is defined as

\[
\omega_T = \frac{(\langle M_T^2 \rangle - \langle M_T \rangle^2)^{1/2}}{\langle M_T \rangle} = \frac{\sigma_{M_T}}{\langle M_T \rangle}. \tag{3.6}
\]

The value of \( \omega_T \) is calculated independently for the data distribution and for the baseline, or mixed event, distribution. The difference in the fluctuation from a random baseline distribution is defined as

\[
d = \omega_{T,\text{data}} - \omega_{T,\text{baseline}}. \tag{3.7}
\]

The sign of \( d \) is positive if the data distribution contains a correlation, such as Bose-Einstein correlations [16], when compared to the baseline distribution. The fraction of fluctuations that deviate from the expectation of statistically independent particle emission is given by

\[
F_T = \frac{(\omega_{T,\text{data}} - \omega_{T,\text{baseline}})}{\omega_{T,\text{baseline}}} = \frac{(\sigma_{T,\text{data}} - \sigma_{T,\text{baseline}})}{\sigma_{T,\text{baseline}}}, \tag{3.8}
\]

where \( \sigma_{T,\text{data}} \) refers to the standard deviation of the event-by-event \( M_T \) data distribution and \( \sigma_{T,\text{baseline}} \) is the corresponding quantity for the baseline, or mixed event, distribution. In the absence of a common language for the analysis of \( M_{p_T} \) and \( M_{e_T} \) fluctuations, the commonly used fluctuation quantity \( \phi_T \) [17] is also presented in order to compare this measurement to previous results [5]. The quantity \( d \) is related directly to \( \phi_T \) via

\[
\phi_T = (\sigma_{T,\text{data}} - \sigma_{T,\text{baseline}}) \sqrt{N_T} = d \langle M_T \rangle \sqrt{N_T}, \tag{3.9}
\]

where \( N_T \) represents \( N_{\text{tracks}} \) or \( N_{\text{clus}} \). The quantity \( \phi_T \) is related to \( F_T \) by

\[
\phi_T = F_T \sigma_{T,\text{baseline}} \sqrt{N_T}. \tag{3.10}
\]

The residual distribution between the data and mixed event \( M_{e_T} \) spectra as a function of \( M_{e_T} \) in units of standard deviations for all centrality classes. The total \( \chi^2 \) and the number of degrees of freedom for the 0–5 %, 0–10 %, 10–20 %, and 20–30 % centrality classes are 310.0/32, 896.4/36, 678.7/47, and 553.9/53, respectively. A large fraction of the residual contributions are due to the effects of cluster merging.

![FIG. 6. The residual distribution between the data and mixed event \( M_{e_T} \) spectra as a function of \( M_{e_T} \) in units of standard deviations for all centrality classes.](image)

The standard deviation of the semi-inclusive spectra can be approximated by $\sigma(T,\text{incl}) = \sigma(T,\text{baseline}) \sqrt{N_T}$ [15], where $\sigma(T,\text{incl})$ is the standard deviation of the semi-inclusive distribution as defined in Eq. (3.3). Therefore, $\phi_{e_T}$ is simply the fraction of nonrandom fluctuations in the event-by-event mean $p_T$ or $e_T$, $F_T$, scaled by $\sigma(T,\text{incl})$. An advantage of $F_T$ over $\phi_{e_T}$ is that measurements expressed in $F_T$ can be directly compared without further scaling.

The magnitudes of any nonrandom fluctuations are established by comparing the data distributions to the mixed event distributions, which serve as the random baseline distributions. For this purpose, the mixed event distributions are normalized to minimize the $\chi^2$ value with respect to the data distributions. Figures 3 and 4 show the $M_{p_T}$ and $M_{e_T}$ distributions for all four centrality classes (data points) with the corresponding mixed event $M_{p_T}$ and $M_{e_T}$ distributions overlaid on the data as dotted curves. The broadening of the distributions for less central collisions is due to the reduction in $\langle N_{\text{clus}} \rangle$ or $\langle N_{\text{clus}} \rangle$. Shown in Fig. 5 and Fig. 6 are the residuals between the data and mixed events, defined for each bin $i$ as residual$_i = (M_T(\text{data}) - M_T(\text{mixed})) / \sigma_T$, in units of standard deviations, for each centrality class. The shapes of the residual distributions are primarily driven by the normalization procedure applied to the mixed events.

For the $M_{p_T}$ distributions, the data and mixed event distributions are indistinguishable. However, the upper $M_{e_T}$ edges of the data and mixed event $M_{e_T}$ distributions show good agreement while the lower $M_{e_T}$ edge of the data distributions are slightly wider than the mixed event distribution. If this low $e_T$ effect were physical, it would imply fluctuations with slightly more low $e_T$ photons since the effect is not seen in the $M_{p_T}$ distribution for charged particle tracks. However, some of the excess fluctuations at low $e_T$ can be attributed to the effects of cluster merging previously discussed. The magnitude of this effect has been investigated using a Monte Carlo simulation which calculates $M_{e_T}$ after reproducing the calorimeter cluster separation distribution, the $N_{\text{clus}}$ distribution, and the semi-inclusive $e_T$ distributions from the data. The fluctuations in the $M_{e_T}$ distribution with this effect included in each event are compared to a simulated mixed event $M_{e_T}$ distribution constructed from the same generated data set using the same procedure that is applied to the data. In this manner, it is estimated that the cluster merging effect contributes an additional $F_T = 1.5\%$, 2.1\%, 0.9\%, and less than 0.01\% to the nonrandom fluctuations for the 0–5\%, 0–10\%, 10–20\%, and 20–30\% centrality classes, respectively. The simulation confirms that the cluster merging effect significantly contributes only to the lower $M_{e_T}$ edge of the distribution. The remainder of the excess low $e_T$ fluctuations is likely due to correlated low energy background. GEANT [19] simulations indicate that the primary background contribution is produced by low energy electrons and muons that scatter off the pole tips of the central arm spectrometer magnet but still pass the cluster selection cuts. Because of the difficulty in quantifying the contribution of background to the excess fluctuations, the present $M_{e_T}$ data are taken to indicate an upper limit on nonstatistical fluctuations rather than an indication of true nonstatistical fluctuations.

The values of $\omega_{e_T}$, $d$, $F_T$, and $\phi_{e_T}$ for each centrality class using the mixed events as the random baseline distribution are tabulated in Table III for $M_{p_T}$ and Table IV for $M_{e_T}$. The errors quoted for these quantities include statistical errors and systematic errors due to time-dependent variations over the data-taking period. The systematic errors are estimated by dividing each data set into nine subsets with each subset containing roughly equal numbers of events. For the $M_{p_T}$ analysis, the systematic errors contribute to 81\%, 88\%, 76\%, and 75\% of the total error in $\omega_{e_T}$ and 85\%, 88\%, 80\%, and 85\% of the total error in the variables $d$, $F_T$, and $\phi_{e_T}$ for the 0–5\%, 0–10\%, 10–20\%, and 20–30\% centrality classes, respectively. The corresponding values for the $M_{e_T}$ analysis are a 67\%, 63\%, 81\%, and 82\% contribution to the total errors in $\omega_{e_T}$, and a 64\%, 63\%, 81\%, and 82\% contribution to the total errors in $d$, $F_T$, and $\phi_{e_T}$ for each centrality class. The cluster merging contribution estimates noted above are not applied to the values quoted in Table IV.

IV. DISCUSSION

Based upon the fluctuation measurements presented here, certain fluctuation scenarios in RHIC Au+Au collisions at $\sqrt{s_{NN}} = 130$ GeV are excluded. For this purpose, we consider two variations of a model that contains two classes of events with a difference of effective temperature, defined as $\Delta T = T_2 - T_1$, where $T_2$ is the inverse slope parameter of the event class with the higher effective temperature, and $T_1$ is the inverse slope parameter of the event class with the lower effective temperature. The first variation, model A, will consider a case where the means of the semi-inclusive $p_T$ spectra for the two event classes are identical, but the standard deviations are different. The second variation, model B, will consider a case where the means of the semi-inclusive $p_T$ spectra are different, but the standard deviations are identical. Since the semi-inclusive $p_T$ distribution is an observed...
The variance of the final semi-inclusive $p_T$ model A is constrained by

$$\Delta \mu = \mu - \mu_1$$

where $T$ parametrized by the event class are constrained to have the same mean, so we $M p_T$ in centrality class as follows. Returning to the prescription outlined of the sensitivity to fluctuations in $p_T$ way that the mean and standard deviation of the final semi-inclusive quantity, the two event classes must be constrained in such a way that the mean and standard deviation of the final semi-inclusive $p_T$ distribution remain constant while the effect of the fluctuation manifests itself in the $M p_T$ distribution.

The dual event class model is applied to the determination of the sensitivity to fluctuations in $M p_T$ for the 0–5% centrality class as follows. Returning to the prescription outlined in [15], the semi-inclusive transverse $p_T$ spectrum can be parametrized by the $f_1(p_T,p,b)$ distribution defined in Eq. (3.1). For both model variations, the fraction of events in the event class with the higher effective temperature is defined as

$$q = \frac{N_{events}}{N_{events}} (\text{class 1}) + N_{events} (\text{class 2}).$$

The $p_T$ distribution of the combined sample can then be expressed as

$$f(p_T) = q \Gamma(p_T,p_1,b_1) + (1 - q) \Gamma(p_T,p_2,b_2),$$

where $T_1 = 1/b_1$ and $T_2 = 1/b_2$.

For model A, the semi-inclusive $p_T$ distributions of each event class are constrained to have the same mean, so we require

$$\mu = p/b = p_1/b_1 = p_2/b_2.$$  

The variance of the final semi-inclusive $p_T$ distribution for model A is constrained by

$$\frac{\sigma^2}{\mu^2} = \frac{1}{p} \left( \frac{q}{p_1} + \frac{(1-q)}{p_2} \right).$$

With these constraints, the choice of a value for $q$ and the effective temperature of one event class is sufficient to extract the remaining parameters from which sensitivity estimates for fluctuations in $M p_T$ are obtained.

For model B, the semi-inclusive $p_T$ distributions of each event class are allowed to have different means, $\mu_1$ and $\mu_2$, so the mean of the total semi-inclusive distribution can be expressed as $\mu = q \mu_1 + (1 - q) \mu_2$. Defining a mean shift $\Delta \mu$ as $\Delta \mu = \mu_2 - \mu_1$, we obtain

$$\mu_2 = \mu + q \Delta \mu.$$  

(4.5)

Allowing $p_1 = p_2$ and applying the constraint that the variances of the two event classes are identical, yields

$$\frac{1}{p_1} = \frac{1/p - q(1-q)(\Delta \mu / \mu)^2}{1 + q(1-q)(\Delta \mu / \mu)^2}.$$  

(4.6)

With a choice of values for $q$ and $\Delta \mu$, the remaining parameters can be calculated, including $\Delta T$.

Both variations of the dual event class model are implemented in a Monte Carlo simulation in the following manner. The number of particles in an event is determined by sampling the $N_{tracks}$ data distribution, approximated by a Gaussian distribution fit to the data. The $p_T$ of each particle in an event is determined individually by sampling the appropriate $\Gamma(p_T,p,b)$ distribution fit to the semi-inclusive $p_T$ data distribution, which yields $p = 0.8$ and $b = 2.46$ for 0–5% centrality. The $p_T$ of each particle is restricted to the $p_T$ range of the measurement. With $N_{tracks}$ and the $p_T$ distribution determined, the $M p_T$ for a given number of events is calculated. The generated $M p_T$ distribution with $q = 0$ for either model variation is found to be statistically consistent with the mixed event $M p_T$ distribution.

The data contain a fraction of background particles that did not originate from the collision vertex that effectively dilute the sensitivity to nonrandom fluctuations. To address this, a fraction of the particles in an event are randomly tagged as background particles, whose $p_T$ distribution is then generated with a separate parametrization prior to calculating $M p_T$ for an event. The level of background contamination is estimated by processing HIJING [18] Au+Au events through a software chain that includes a detailed GEANT simulation [19] with the complete PHENIX detector geometry included, followed by a detailed simulation of the detector electronics response [12], whose output is then processed by track, cluster, and momentum reconstruction using the identical software and input parameters as is used for the data analysis. It is estimated that 11% of the tracks and 26% of the clusters are due to background particles, independent of centrality class over the centrality range of these measurements. The estimated $p_T$ and $e_T$ distributions for the background particles are well parametrized by exponential distributions. Again, the majority of the $e_T$ background occurs at low $e_T$, so any correlated background would most likely contribute to the lower side of the $M e_T$ distribution.
To determine the sensitivity to fluctuations within the dual event class model, the fluctuation fraction $q$ and the value of $p_1$ for model A and $\Delta \mu$ for model B are varied and the $M_{pT}$ distribution is generated at each step. A $\chi^2$ test is then performed on the generated $M_{pT}$ distribution with respect to the mixed event data $M_{pT}$ distribution. For a given value of $q$, the $\chi^2$ result increases as $\Delta T$ increases, which allows a fluctuation exclusion region to be defined for the single degree of freedom. The curves in Fig. 7 show the lower exclusion boundaries for the 0–5% centrality $M_{pT}$ measurement at the 95% confidence level as a function of $q$ and $\Delta T$ for both variations of the model. If the sensitivity is determined based upon the nonmixed data distribution, the lower exclusion boundary increases by less than 2 MeV for all values of $q$ for either model. Also, for all values of $q$ in either model, the estimated background contribution degrades the sensitivity estimates by $\Delta T = 3$ MeV for both models.

A recent model of event-by-event fluctuations where the temperature parameter $T = 1/b$ fluctuates with a standard deviation $\sigma_T$ on an event-by-event basis [20] can be simply related to $F_T$:

$$\frac{\sigma_T^2}{\langle T \rangle^2} = \frac{2F_T}{p\langle n \rangle - 1}, \quad (4.7)$$

where $p = 0.8$ is the semi-inclusive parameter extracted from the present data. For the 0–5% centrality class, the present measurement establishes a 95% confidence limit of 2.6 $\times 10^{-3}$ for $\sigma_T^2/\langle T \rangle^2$, or 5% for $\sigma_T/\langle T \rangle$.

V. CONCLUSIONS

The fluctuations in the $M_{pT}$ distributions for all centrality classes are consistent with the presence of no fluctuations in excess of the random expectation. The magnitude of $F_T$ in all cases is positive, which may be due to the presence of Hanbury-Brown-Twiss correlations. The fluctuations in the $M_{eT}$ distributions do have a small nonstatistical component, much of which is attributable to the effects of merged clusters, the remainder of which are taken to indicate an upper limit on nonstatistical fluctuations in transverse energy. By defining a dual event class model, limits are set on the amount of $M_{pT}$ fluctuations that can be present in the angular aperture $|\eta| < 0.35$ and $\Delta \phi = 58.5^\circ$ in $\sqrt{s_{NN}} = 130$ GeV Au+Au collisions. During the RHIC run of 2001, PHENIX has taken data for $\sqrt{s_{NN}} = 200$ GeV Au+Au collisions with about a factor of 4 increase in azimuthal angular acceptance for both the $M_{pT}$ and $M_{eT}$ analyses, which will allow the measurements to be extended toward more peripheral collisions.
