Flow measurements via two-particle azimuthal correlations in Au plus Au collisions at root S-NN=130 GeV

Abstract
Two-particle azimuthal correlation functions are presented for charged hadrons produced in Au + Au collisions at the Relativistic Heavy Ion Collider (roots(NN) = 130 GeV). The measurements permit determination of elliptic flow without event-by-event estimation of the reaction plane. The extracted elliptic flow values (upsilon(2)) show significant sensitivity to both the collision centrality and the transverse momenta of emitted hadrons, suggesting rapid thermalization and relatively strong velocity fields. When scaled by the eccentricity of the collision zone epsilon, the scaled elliptic flow shows little or no dependence on centrality for charged hadrons with relatively low p(T). A breakdown of this epsilon scaling is observed for charged hadrons with p(T) > 1.0 GeV/c.

Two-particle azimuthal correlation functions are presented for charged hadrons produced in Au + Au collisions at the Relativistic Heavy Ion Collider ($\sqrt{s_{NN}} = 130 \text{ GeV}$). The measurements permit determination of elliptic flow without event-by-event estimation of the reaction plane. The extracted elliptic flow values ($v_2$) show significant sensitivity to both the collision centrality and the transverse momenta of emitted hadrons, suggesting rapid thermalization and relatively strong velocity fields. When scaled by the eccentricity of the collision zone ε, the scaled elliptic flow shows little or no dependence on centrality for charged hadrons with relatively low $p_T$. A breakdown of this ε scaling is observed for charged hadrons with $p_T > 1.0 \text{ GeV/c}$.

\[ \frac{dN}{d(\phi - \Phi_R)} \propto \left( 1 + \sum_{n=1}^{\infty} 2v_n \cos(n(\phi - \Phi_R)) \right). \]  

The primary goal of current relativistic heavy ion research is the creation and study of nuclear matter at high energy densities [1–7]. Open questions include the detailed properties of such excited matter, as well as the existence of a transition to the quark-gluon plasma (QGP) phase. Such a phase of deconfined quarks and gluons has been predicted to survive for $t \approx 3–10 \text{ fm}/c$ in Au + Au collisions at the Relativistic Heavy Ion Collider (RHIC) [8], and several experimental probes have been proposed for its possible detection and study [1]. Elliptic flow constitutes an important observable [9–16] because it is thought to be driven by pressure built up early in the collision and, therefore, can reflect conditions existing in the first few fm/c. Elliptic flow leads to an anisotropy in the azimuthal distribution of emitted particles. A Fourier decomposition of this distribution [17,18],

\[ \frac{dN}{d(\phi - \Phi_R)} \propto \left( 1 + \sum_{n=1}^{\infty} 2v_n \cos(n(\phi - \Phi_R)) \right). \]  

DOI: 10.1103/PhysRevLett.89.212301 PACS numbers: 25.75.Ld
provides a characterization of the elliptic flow via the second Fourier coefficient \( v_2 \). Here, \( \phi \) is the azimuthal angle of an emitted particle and \( \Phi_R \) is the azimuth of the reaction plane, defined by the beam direction and the impact-parameter vector [19]. The apparent reaction plane is determined from the azimuthal correlations between emitted particles, and its dispersion correction from the azimuthal correlations between two “sub-events” [19–21]. An alternative technique for elliptic flow analysis is the Fourier decomposition of the pairwise distribution in the azimuthal angle difference \( (\Delta \phi = \phi_1 - \phi_2) \) between pairs of emitted particles [22–24]:

\[
\frac{dN}{d\Delta \phi} \propto \left( 1 + \sum_{n=1}^{\infty} 2v_n^2 \cos(n\Delta \phi) \right).
\]

In this case the magnitude of the elliptic flow is characterized by the square of the second Fourier coefficient in Eq. (1), i.e., \( v_2^2 \). These methods of analysis can be taken as equivalent since (i) the correlation between every particle and the reaction plane induces correlations among the particles, and (ii) correlating two subevents amounts to summing two-particle correlations [18]. The results in this Letter have several advantages over elliptic flow measurements obtained via the reaction plane method at the same beam energy by the STAR [5] and PHOBOS [6] Collaborations. First, two-particle correlations circumvent the need for full azimuthal detector acceptance. Second, it allows the determination of elliptic flow without event-by-event estimation of the reaction plane and the associated corrections for its dispersion. Third, the correlation method can provide insights on nonflow correlations and minimize many important systematic uncertainties (detector acceptance, efficiency, etc.) important to the accuracy of elliptic flow measurements [22,23,25].

Elliptic flow is predicted and found to be negative for beam energies \( \leq 44 \) GeV and positive for higher beam energies in \( Au + Au \) collisions [9,13–16]. Recent theoretical investigations have made predictions for the centrality dependence of the scaled elliptic flow \( A_2 \equiv \frac{v_2}{v_0} \) [26,27], where \( v_0 \) is the eccentricity or initial spatial anisotropy of the “participant” nucleons in the collision zone. The eccentricity \( v_0 \) shows an essentially linear variation with impact parameter \( b \), for \( 0.2b_{max} \leq b \leq 0.8b_{max} \) [9] in \( Au + Au \) collisions \( (b_{max} \approx 14 \) fm). For central collisions \( (b \leq 5–6 \) fm), it is predicted that higher energy densities are produced and rapid kinetic equilibration in the QGP phase leads to a characteristic rise in \( A_2 \) [26,27]. In addition, elliptic flow for high \( p_T \) particles has been proposed as an observable sensitive to the energy loss of scattered partons in a QGP phase [28].

The colliding \( Au \) beams \( (\sqrt{s_{NN}} = 130 \) GeV) used in these measurements have been provided by the Relativistic Heavy Ion Collider at Brookhaven National Laboratory (BNL). Charged reaction products were detected in the east and west central arms of the PHENIX detector [2,29]. Each of these arms subtends 90° in azimuth \( \phi \) and ±0.35 units of pseudorapidity \( \eta \). The axially symmetric magnetic field of PHENIX (0.5 T) allowed for the tracking of particles with \( p_T \approx 200 \) MeV/c in the fiducial volume of both arms. The drift chamber (DC) and a layer of pad chambers (PC1) located at radii of 2 m and 2.5 m, respectively, in each arm, served as the primary tracking detector for these measurements. A second layer of pad chambers (PC3), positioned at 5 m in the east arm, was employed to confirm the trajectory of charged particles which traversed both the DC and PC1. The zero degree calorimeters (ZDC) were used in conjunction with the beam-beam counters (BBC) to provide the position of the vertex along the beam direction as well as a trigger for a wide range of centrality selections.

The present data analysis uses two-particle azimuthal correlation functions to measure the distribution of the azimuthal angle difference \( (\Delta \phi = \phi_1 - \phi_2) \) between pairs of charged hadrons. Following an approach commonly exploited in interferometry studies, a two-particle azimuthal correlation function can be defined as follows [22–24]:

\[
C(\Delta \phi) = \frac{N_{cor}(\Delta \phi)}{N_{uncor}(\Delta \phi)},
\]

where \( N_{cor}(\Delta \phi) \) is the observed \( \Delta \phi \) distribution for charged particle pairs selected from the same event, and \( N_{uncor}(\Delta \phi) \) is the \( \Delta \phi \) distribution for particle pairs selected from mixed events. Events were selected with a collision vertex position, \( -20 < z < 20 \) cm, along the beam axis. Mixed events were obtained by randomly selecting each member of a particle pair from different events having similar multiplicity and vertex position. In order to suppress an overefficiency in finding two tracks at close angles, hadron pairs within 1 cm of each other in the DC were removed from both the \( N_{cor}(\Delta \phi) \) and \( N_{uncor}(\Delta \phi) \) distributions. Event centralities were obtained via a series of cuts in the space of BBC versus ZDC analog response [2]; they reflect percentile selections of the total interaction cross section of 6.8 b [2]. Estimates for the impact parameter and the eccentricity, \( \varepsilon = \left< (y^2) - \left< x^2 \right> \right> / \left< (y^2) + \left< x^2 \right> \right> \), were also made for each of these selections following the model detailed in Ref. [2]. Here, \( \left< \ldots \right> \) represents the spatial average (weighted by the density) of participant nucleons over the transverse plane of the collision zone [11]. Systematic uncertainties associated with the determination of \( \varepsilon \) are estimated to be \( \sim 7\% \). This estimate includes the variation of all of the inputs to the Glauber model within reasonable limits.

Correlation functions were obtained via two separate methods. In the first, charged hadron pairs were formed by selecting each particle from a common \( p_T \) range (fixed-\( p_T \) method). In the second hadron pairs were formed by selecting one member from a fixed \( p_T \) range.
and the other from outside this range (assorted-$p_T$ method). Within statistical errors, both methods of analysis yield similar results for the $p_T$ range presented below, as would be expected for a system dominated by collective motion.

An important prerequisite for reliable flow extraction from PHENIX data is to establish whether or not the $\sim 180^\circ$ azimuthal coverage of the detector results in significant distortions to the correlation function. To this end, detailed simulations of the detector response, acceptance, and efficiency, have been performed for simulated data incorporating specific amounts of flow (parameterized by $v_2$). The results from these simulations indicated no significant distortion to the correlation functions due to the PHENIX acceptance. On the other hand, small distortions to the correlation function (for $\Delta \phi \leq 25^\circ$) as well as an incomplete recovery of $v_2$ could be attributed to background contributions from particle decay and interactions in detector material.

These background contributions principally affect the extraction of $v_2$ from the correlation function in two ways. The distortion to the correlation function at small relative angle introduces a small systematic distortion when fit with a Fourier function [cf. Eq. (2)]. A good representation of the data was obtained with the fit function $C(\Delta \phi) = \lambda \exp[-0.5(\Delta \phi/\sigma)^2] + a_1[1 + 2v_2^{a} \cos(2\Delta \phi)]$, where the Gaussian term is used to characterize the background distortion at small angles. In addition, there is an isotropic background of false tracks which are predominantly misidentified as high $p_T$ particles. These contributions can be efficiently suppressed in the east central arm of PHENIX, by requiring a relatively stringent association between tracks found in the DC and their associated hits in PC3. Using such a procedure, the fraction of background tracks has been evaluated as a function of $p_T$ and used to correct $v_2$. Corrections range from $\sim 10\%$ at low $p_T$ to $\sim 25\%$ at 2 GeV/$c$ with a systematic uncertainty of 5%. The current analysis is restricted to the range $0.3 < p_T < 2.5$ GeV/$c$ to maintain this relatively small systematic uncertainty.

Figures 1(a)–1(d) show representative $\Delta \phi$ correlation functions obtained for charged hadrons detected in the pseudorapidity range $-0.35 < \eta < 0.35$. Correlation functions for relatively central events (centrality = 20%–25%, $b \sim 7.0$ fm) are shown for hadrons with $0.3 < p_T < 2.5$ GeV/$c$ and $0.5 < p_T < 2.5$ GeV/$c$ in Figs. 1(a) and 1(c), respectively. The same $p_T$ selections have been made for the correlation functions shown in Figs. 1(b) and 1(d) but for more peripheral collisions (centrality = 40%–45%, $b \sim 9.6$ fm) as indicated. Figures 1(a)–1(d) show a clear anisotropic pattern which is essentially symmetric about $\Delta \phi = 90^\circ$. There is also a visible increase of this anisotropy with increasing impact parameter and $p_T$. These trends are all consistent with those expected for in-plane elliptic flow [10,11,13,20].

The magnitude of elliptic flow and the mechanism for its development can be shown to be related to (a) the geometry of the collision zone, (b) the initial baryon and energy density developed in this zone, and (c) the detailed nature of the equation of state for the created nuclear matter [9–13,26]. Since differential flow measurements can serve to provide important insights for disentangling these separate aspects [10–13,26], we show the results of such measurements in Figs. 2 and 3. Figure 2 shows $v_2$ as a function of centrality for several $p_T$ selections: $0.40 < p_T < 0.60$ GeV/$c$ (diamonds), $0.60 < p_T < 1.00$ GeV/$c$ (squares), and $1.0 < p_T < 2.5$ GeV/$c$ (circles), respectively. Figure 3 compares the differential flow $v_2(p_T)$ for several centralities as indicated.
Figures 2 and 3 both show relatively large differential flow values which increase with increasing impact parameter and the $p_T$ of emitted hadrons. The separate effects of spatial asymmetry and the response of the collision zone, possibly due to the generated pressure are also evident in Fig. 2. That is, $v_2$ not only increases with increasing impact parameter for a fixed $p_T$, but also increases with increasing $p_T$ for a fixed centrality selection. Trivially, the magnitude of flow should go to zero for very small and very large impact parameters. Similarly, its magnitude can be expected to be zero for $p_T = 0$. It is interesting that Fig. 3 indicates an essentially linear rise of $v_2$ with $p_T$ for each of the centrality selections presented. Such a trend cannot be accounted for via simple geometric considerations alone [30]. However, it is compatible with model calculations which assume a strong transverse velocity field [30]. This suggests the presence of strong dynamically driven transverse flow at RHIC. The magnitude and trends for $v_2$ shown in Figs. 2 and 3 are consistent with other elliptic flow measurements at RHIC [5,6].

Figure 4 aims to disentangle the geometric and dynamical ($p_T$) contributions to the elliptic flow over a broad range of centralities or energy densities. To do this, we plot $A_2$ as a function of centrality to obtain the dynamical contributions [26,27]. This evaluation is performed for two $p_T$ selections ($0.4 < p_T < 0.6$ and $1.0 < p_T < 2.5$ GeV/$c$) which give rise to relatively low and high $p_T$ values, respectively. The underlying idea is that this ratio should remove the geometric dependence of $v_2$, while the $p_T$ selections may provide greater sensitivity to different time scales and energy densities associated with the expanding system.

Figure 4 shows an increase in the magnitude of $A_2$ with increasing $p_T$. This increase can be attributed to the dynamical response of the created system, resulting from the generated pressure gradients. For hadrons of $0.4 < p_T < 0.6$ the observed centrality dependence of $A_2$ is compatible with $e$ scaling. However, a breakdown of this scaling is observed for hadrons with $1.0 < p_T < 2.5$. Such a trend may point to a change in the particle production mechanism or the possibility that pressures larger than those predicted by current hydrodynamic calculations [10,11] are being produced in the most central collisions at RHIC. It is also interesting to note that the species’ composition of the charged particle spectra changes dramatically between the two $p_T$ ranges used in Fig. 4 [31].

To summarize, we have measured two-particle azimuthal correlation functions for charged hadrons produced in Au + Au collisions at RHIC ($\sqrt{s_{NN}} = 130$ GeV). The integral, differential, and scaled elliptic flow values extracted from these measurements indicate strong sensitivity to the collision centrality and the transverse momenta of emitted hadrons. The centrality dependence of $v_2$ suggests that the high-energy-density nuclear matter created at RHIC efficiently translates the initial spatial asymmetry into a similar asymmetry in momentum space. The $p_T$ dependence is consistent with the development of strong transverse velocity fields in the collision zone. The centrality dependence of $A_2$ for hadrons in the range $0.4 < p_T < 0.6$ is compatible with $e$ scaling. However, a breakdown of this scaling is observed for hadrons with $1.0 < p_T < 2.5$. Such a trend could result from a number of effects, the most intriguing of which is a possible change in the equation of state [26,27].

Additional experimental signatures and model calculations will undoubtedly be necessary to test the detailed implications of these results. Nevertheless, the results presented here clearly show that two-particle azimuthal
correlation measurements provide an important probe for the high-energy-density nuclear matter created at RHIC.
