This Dissertation is brought to you for free and open access by the Iowa State University Capstones, Theses and Dissertations at Iowa State University Digital Repository. It has been accepted for inclusion in Retrospective Theses and Dissertations by an authorized administrator of Iowa State University Digital Repository. For more information, please contact digirep@iastate.edu.
INFORMATION TO USERS

This was produced from a copy of a document sent to us for microfilming. While the most advanced technological means to photograph and reproduce this document have been used, the quality is heavily dependent upon the quality of the material submitted.

The following explanation of techniques is provided to help you understand markings or notations which may appear on this reproduction.

1. The sign or "target" for pages apparently lacking from the document photographed is "Missing Page(s)". If it was possible to obtain the missing page(s) or section, they are spliced into the film along with adjacent pages. This may have necessitated cutting through an image and duplicating adjacent pages to assure you of complete continuity.

2. When an image on the film is obliterated with a round black mark it is an indication that the film inspector noticed either blurred copy because of movement during exposure, or duplicate copy. Unless we meant to delete copyrighted materials that should not have been filmed, you will find a good image of the page in the adjacent frame.

3. When a map, drawing or chart, etc., is part of the material being photographed the photographer has followed a definite method in "sectioning" the material. It is customary to begin filming at the upper left hand corner of a large sheet and to continue from left to right in equal sections with small overlaps. If necessary, sectioning is continued again—beginning below the first row and continuing on until complete.

4. For any illustrations that cannot be reproduced satisfactorily by xerography, photographic prints can be purchased at additional cost and tipped into your xerographic copy. Requests can be made to our Dissertations Customer Services Department.

5. Some pages in any document may have indistinct print. In all cases we have filmed the best available copy.

1. A REVIEW OF DENSITY ESTIMATION METHODS

1.1. Introduction

Density estimation is possibly the most important topic in applied statistics. When we do not know the density, \( f(x) \), we must infer its characteristics from a sample \( X_1, X_2, \ldots, X_n \) before we can make any inferences or predictions. Classical density estimation involves initial screening of the data, which leads to hypothesizing that the data came from a particular parametric family of density curves. The process of estimating the parameters of that family of densities and hypothesis testing to see if this hypothesis is tenable follows. In the absence of a priori information, the initial screening of the data is usually done with the time honored histogram which leaves a lot to be desired as a density estimate. It was in 1951 that Fix and Hodges (1951) suggested some improvement in the method of producing a histogram, reducing the subjectivity to some extent. This soon led to nonparametric estimates of \( f(x) \) which are continuous and, so to some extent, could bypass the usual inference chain of parametric density estimation.

The estimators suggested fall roughly into the following categories:

(a) kernel (or window) estimators,

(b) spline estimators,

(c) series estimators,
(d) maximum likelihood, and histogram type estimators.

We shall examine these nonparametric methods of univariate density estimation in this chapter. Chapter 2 takes a closer look at kernel density estimators, nearest neighbor estimators in particular, and develops two new estimators. Chapter 3 presents simulation results for these estimators and compares their performance to some kernel estimators.

1.2. Kernel Density Estimators

Fix and Hodges (1951), in a paper on nonparametric discrimination, used a "running histogram" as a density estimate rather than assume an underlying normal distribution or choose the usual histogram. They subjectively chose an interval width, h, and then estimated the density at any given point as being proportional to the number of observations falling within an interval of width h centered at the point under consideration. This running histogram, or naive estimator led Rosenblatt (1956) to define a class of univariate estimators, known as kernel, or window, estimators, which can be written as

\[
\hat{f}_n(x) = \frac{1}{nh} \sum_{i=1}^{n} K\left(\frac{x-X_i}{h}\right)
\]  

(1.2.1)

where \(X_1, X_2, \ldots, X_n\) are assumed to be independently and identically distributed with \(f(\cdot)\), the unknown density and
$K(\cdot)$ is the kernel. For the naive estimator,

$$K(x) = \frac{1}{2} \text{ for } |x| \leq 1$$

$$= 0 \text{ otherwise.} \quad (1.2.2)$$

The larger the value of $h$, the coarser the grouping, so that as $n$ becomes large, $h$ should become smaller. If, the kernel $K$ satisfies the following conditions:

- $K$ is symmetric
- \[\int K(u)\,du = 1\]
- \[\int K^2(u)\,du < \infty \quad (1.2.3)\]
- \[\int K(u)|u|^3\,du < \infty,\]

then Rosenblatt, showed that this class of estimators was pointwise and integratedly consistent in quadratic mean provided $h = h_n$ is chosen suitably. The optimal choice of $h_n$, which depends on the unknown density $f$, leads to the convergence of the MSE, the mean squared error, at the rate of $0(n^{-4/5})$. Parzen (1962) imposing further constraints on $K$, showed asymptotic unbiasedness, and then listed several forms of the kernel which satisfy these constraints. The kernels considered include the rectangular, triangular, normal
and Cauchy density functions. If

\[ h_n \to 0 \]

and

\[ nh_n \to \infty, \quad (1.2.4) \]

he also showed that the MSE converges to zero, and under further conditions, showed the asymptotic normality of \( \{\hat{f}_n(x)\} \) for fixed \( x \). Many authors followed Parzen's approach, changing the assumptions about \( f(x) \), the conditions imposed on \( K(\cdot) \), and \( \{h_n\} \), and proved consistency properties for \( \hat{f}_n \). Amongst them are Nadaraya (1963, 1965), Murthy (1965), Woodroofe (1967), Bhattacharya (1967), Schuster (1969, 1970) and Silverman (1978a), Craswell (1965) generalized Parzen's results to estimation on a topological group, and Borwanker (1971) considered strictly stationary processes.

Other authors found asymptotically optimal forms for \( K(\cdot) \), the kernel. Bartlett (1963), for example, proposed

\[ K(u) = \frac{9}{8h}(1 - \frac{5u^2}{3h^2}) \quad \text{for} \quad |u| \leq h \]

\[ = 0 \quad \text{otherwise}, \quad (1.2.5) \]

which optimizes a larger group of terms in the asymptotic expansion of the mean squared error. Watson and Leadbetter (1963) used the integrated mean squared error as a criterion and arrived at
\[ \phi_K(t) = \frac{|\phi_f(t)|^2}{\left( \frac{1}{n} + \frac{1}{\sqrt{\phi_f(t)}} \right) \left( \frac{n-1}{n} \right)} \]  

where \( \phi_f(t) \) is the Fourier transform of \( f( \cdot ) \), assuming \( \phi_f \) to be square integrable. They demonstrated the optimal form for \( K \) corresponding to various densities \( f \) and showed that the integrated mean squared error cannot be better than \( O(1/n) \). Woodroofe (1968) presented a two-stage procedure to estimate \( f( \cdot ) \) when the kernel \( K \) has been specified. After two initial guesses for \( h_n \), which are used to obtain rough estimates for \( f \) and the first nonvanishing moment of \( f \), a new value \( h_n \) for \( h \) is computed. This \( h_n \) is used to estimate \( f( \cdot ) \) in the usual way. Woodroofe showed that this method converged asymptotically in mean squared error. Nadaraya (1974) provided a similar two-stage procedure, but was based on a different optimality criterion. Whittle (1958) suggested a linear estimator of \( f(x) \) of the form

\[ \hat{f}(x) = \frac{\sum W(x_i)}{N} \]  

where \( W \) is a weight function to be optimized and then considered a Poissonization of the problem. Consider \( N \) to be distributed as Poisson (\( M \)) and estimate \( \phi(x) = Mf(x) \) by

\[ \hat{\phi}(x) = \frac{\sum W(X_i) \cdot M}{N} \]  

(1.2.8)
using as an optimization criterion

$$\min_{\phi, \epsilon \phi} E_{\phi, \epsilon \phi} |\hat{\phi}(x) - \phi(x)|^2.$$  \hspace{1cm} (1.2.9)

The suffices in (1.2.9) refer to the prior distribution of the parameters and the sampling fluctuations, respectively. Anderson (1969a,b), after a fairly extensive study, concluded that the actual kernel \(K(\cdot)\) used makes little difference to the optimum value of the integrated mean squared error, but that the optimal value of \(h_n\) differs for different kernels. The normal kernel performs satisfactorily when estimating normal and relatively symmetric densities, but not when estimating the negative exponential. Fryer (1977) recommended that skew data should be transformed nearer to symmetry before using the estimation procedure, and then the resulting estimate should be transformed back. Nadaraya (1964) and Watson (1964) considered estimating the regression curve of \(Y\) on \(X\),

$$E(Y|X) = \frac{\int yf(x,y)dy}{\int f(x,y)dy} \equiv m(x).$$ \hspace{1cm} (1.2.10)

As an estimator, they used

$$\hat{m}(x) = \frac{1}{n} \sum_{i=1}^{n} \frac{Y_i}{\frac{x-X_i}{h}} K\left(\frac{x-X_i}{h}\right).$$ \hspace{1cm} (1.2.11)
with a symmetric $K(\cdot)$ and proved some asymptotic results. In a later paper, Nadaraya (1965) considered the regression problem of $Y$ on $X$ where

$$X = Y + Z, \quad Z \sim N(0, \sigma^2),$$

(1.2.12)

and the density of $Y$ being unknown. Since

$$E(Y | X) = \frac{\sigma^2 f'(x)}{f(x)} + x,$$

(1.2.13)

he proposed

$$\hat{m}(x) = \sigma^2 \frac{\psi_n(x)}{\hat{f}_n(x)} + x,$$

(1.2.14)

$$\psi_n(x) = \frac{\hat{f}_n(x+h) - \hat{f}_n(x-h)}{2h}$$

and proved some consistency properties with

$$h_n = n^{-\theta}, \quad 0 < \theta < \frac{1}{2}.$$  

(1.2.15)

Another group of papers is concerned with estimating the hazard function

$$z(x) = \frac{f(x)}{1 - F(x)}.$$  

(1.2.16)

Watson and Leadbetter (1964a,b) used as estimators,

$$\hat{z}_n(x) \left( \frac{\hat{f}_n(x)}{1 - \int_0^x \hat{f}_n(t) dt} \right)$$

(1.2.17)
and

\[ \frac{f_n(x)}{1-F_n(x)'}, \]

\( F_n(\cdot) \) being the sample distribution function. Both the estimators are asymptotically unbiased under suitable conditions.

Nearest neighbor estimators, which are kernel estimators also, are considered in Chapter 2.

1.3. Spline Estimators

Boneva, Kendall and Stefanov (1971) used the histogram as a starting point for a smoothed estimator of an unknown probability density function. Starting with the data in the form of a histogram, with the cell width \( \varepsilon \) specified, they found a one to one, linear invariant and bi-continuous mapping onto a Hilbert space of smooth functions and called the resulting form a histospline. The histospline is a quadratic spline, i.e., a continuous and continuously differentiable function which is a quadratic in each fixed interval and square integrable. It is also constrained to integrate to the same value as the original histogram over every cell, but is not necessarily nonnegative. To apply it to raw data, it can be written in the form of a kernel estimator and hence enjoys the attributes of that class of
estimators. Schoenberg (1972) and Lii and Rosenblatt (1975) presented similar modifications of the histospline estimator, producing a less wiggly and nonnegative estimator. Wahba (1975) considered the statistical properties of a slight generalization of the histospline for densities with finite support. Instead of the second derivatives being assumed zero at the end points of the interval, their values can be estimated from the data.

Wahba (1971) considered another approach. A local estimate of \( f \) at \( x \) can be based on the derivative of an \( m \)th degree polynomial estimate of \( F \) in the neighborhood of \( x \) obtained by the Lagrangian interpolation formulae. Wahba showed that this estimator is pointwise consistent in mean squared error at a slightly faster rate than the kernel estimators under stated conditions. Van Ryzin (1969) earlier had derived a special case of this estimator.

1.4. Series Estimators

Let \( X_1, X_2, \ldots, X_n \) be independently and identically distributed with the unknown probability density function, \( f(x) \), \( x \in \mathbb{R} \). Let \( r(\cdot) \) be a known weight function so that the inner product
\[ (\phi, \psi) = \int_{\mathbb{R}} \phi(x)\psi(x)r(x)\,dx \]  

defines a Hilbert space \( L_2(r) \) and let an orthonormal basis \( \{\phi_{R,N}\}, k=1,2,\ldots,N \) exist for the \( N \)-dimensional subspace \( E_n \), then

\[ f_n(x) = \sum_{k=1}^{N} a_{k,N} \phi_{k,N} \]

\[ = \sum_{k=1}^{N} (\phi_{k,N}, f) \phi_{k,N} \]  

(1.4.2)

is the mean squared approximation to \( f(x) \). Cencov (1962a,b) considered

\[ a_{k,N}^* = \frac{1}{n} \sum_{i=1}^{n} \phi_{k,N}(x_i)r(x_i) \]  

(1.4.3)

as a strongly consistent estimator for \( a_{k,N} \) and proposed

\[ \hat{f}_n(x) = \sum_{k=1}^{N} a_{k,N}^* \phi_{k,N} \]  

(1.4.4)

as an estimator for \( f(x) \). The choice of \( E_n \) and \( n \) contribute to the closeness of \( f_n(x) \) to \( f(x) \). He proved several theorems relating to the degree of approximation and proposed a stopping rule for \( N \), the number of terms in the series. The resulting estimator is not necessarily always nonnegative. Several authors considered the same formulation as Cencov and studied the properties of the resulting estimators. Schwartz (1967)
considered the case when \( r(x) = 1 \), \( N = N(n) \) and \( \phi_k(\cdot) \) is the
kth Hermite function over the real line and proved several
consistency properties requiring conditions such as \( \frac{N}{n} \to 0 \) as
\( n \to \infty \). Blaydon (1967) considered a generalization, estimating
both \( F(\cdot) \) and \( f(\cdot) \) by a linear combination of functions using
the criterion of minimum least squares. Kashyap and Blaydon
(1968) evaluated \( a_{kN}^* \) by a gradient type technique and gave
an example using the first three Laguerre polynomials over
\([0,4]\) to estimate the distribution function corresponding to
an exponential density. Watson (1969) introduced a general
weight function \( \lambda \) in the estimator,

\[ \hat{F}_n(x) = \sum_{k=1}^{\infty} \lambda_k(N) a_{kN} \phi_{k,N}(x); \]  

however,

\[ \lambda_k(N) = 1, \text{ for } k = 1,2,\ldots,n \]

\[ = 0 \quad \text{elsewhere} \]

is a better form as far as application is concerned.

Tarter and Kronmal (1967) extend the Cencov model
to cover both \( F(\cdot) \) and \( f(\cdot) \), but only with finite support.
They chose the trigonometric functions \{\cos k\pi x\}, \{\sin k\pi x\},
and \{\cos k\pi x, \sin k\pi x\} for their \( \phi \)'s, as they require the
orthogonal series used to estimate \( F(\cdot) \), still to be ortho­
gonal when differentiated to yield the estimate for \( f(\cdot) \).
They give a stopping rule for the number of terms to be
included in the series and suggest that ten should be sufficient for all practical purposes. Fellner (1974), in a synthesis of the papers by Whittle (1958), Tarter and Kronmal (1967) produced a multistep estimating procedure which bypassed the usual stopping rule problem by using a hypothesis testing technique. Crain (1974) proposed a maximum likelihood approach to estimating the coefficients of the orthogonal series. Several authors, e.g. Watson (1969), Fellner and Tarter (1971), and Tarter and Raman (1971), noted the theoretical equivalence under stated conditions of the Fourier estimators and kernel estimators, but in practice, the resulting estimators are locally very different, especially when $n$ is relatively small.

1.5. Maximum Likelihood Estimators

Wegman (1969; 1970a,b) employed a maximum likelihood approach to obtain a modified histogram estimator for an unknown density $f$ with domain $(a,b]$. His estimators are of the form

$$f(x|c) = \sum_{j=0}^{k-1} c_j I(a_j, a_{j+1})(x), \quad (1.5.1)$$
where

\[ I(c, d)(x) = 1 \text{ if } x \in (c, d) \]
\[ = 0 \text{ otherwise,} \]

\[ c_j > 0, \quad j = 0, 1, \ldots, k, \]
\[ \sum_{j=0}^{k-1} c_j (a_{j+1} - a_j) = 1, \]
\[ a_0 = a \]
\[ a_k = b \]
\[ c = (c_1, c_2, \ldots, c_k). \]

The criterion function to be maximized based on a sample of size \( n \), \( \{x_1, x_2, \ldots, x_n\} \) is

\[ L(c) = \prod_{i=1}^{n} \hat{f}(x_i/c), \]  \hspace{1cm} (1.5.2)

subject to the constraint that at least \( m(n) \) observations must fall into each of the \( k \) intervals where

\[ k \leq [\frac{n}{m(n)}] \text{ and } \]
\[ m(n) \rightarrow \infty \text{ faster than } O(\sqrt{\log(\log n)}). \]  \hspace{1cm} (1.5.3)

For \( k = nm(n) \), the solution is
\[
\hat{f}(x) = \frac{1}{k} \sum_{j=0}^{k-1} \frac{1}{a_{j+1} - a_j} \mathbb{I}(a_j, a_{j+1})(x),
\]

\[
a_0 = a_1 = X_{(1m)}
\]
\[
a_2 = X_{(2m)}
\]
\[
a_{k-1} = X_{(k-1)m}
\]

and
\[
a_k = b.
\]

Thus, Wegman used interval widths of the histogram, which varied across the data base in a manner inversely proportional to the density of the data points in the interval. This approach to density estimation, maximizing the likelihood function over a certain space, was initially proposed by Grenander (1956). He derived the maximum likelihood estimate for a nonincreasing density \( f(\cdot) \) corresponding to an absolutely continuous distribution function, \( F(\cdot) \). It arose from the studies of the force of mortality determined from mortality tables. He showed the estimate \( \hat{f}_n(\cdot) \) to be a step function, the derivative of the greatest convex minorant of the empirical distribution function. Other authors who have used similar techniques are Marshall and Proschan (1965), Robertson (1967), Weiss and Wolfowitz (1967), Rao (1969), McGilchrist (1975).

Good (1971) and Good and Gaskins (1971, 1972) considered maximizing a score function
\[ \omega = L - \phi(f), \] (1.5.5)

where \( L \) is the sample log likelihood function and \( \phi \) a non-negative roughness penalty function. They proved pointwise consistency in probability under stated conditions. They let

\[ \phi(f) = 4\alpha \int y^2 \, dx + \beta \int y'^2 \, dx. \] (1.5.6)

where

\[ f = y^2, \]
\[ \alpha > 0, \]
\[ \beta > 0, \]
\[ \alpha + \beta > 0, \]

and assumed

\[ \gamma(x) = \Sigma_{m=0}^{\infty} \gamma_m \phi_m(x), \] (1.5.7)

\( \gamma_m \) are real coefficients and \( \phi_m(x) \) are the Hermite polynomials. This leads to a set of simultaneous nonlinear equations to be solved iteratively for \( \gamma_1, \gamma_2, \ldots, \gamma_R \), where \( \gamma_{R+1}, \ldots \), are assumed zero.

1.6. Remarks

So far, we have discussed various methods of density estimation. One method not yet mentioned is a subclass of kernel estimators. In kernel density estimators, regardless of the point at which the density is to be estimated, the
window used is the same for a given sample size. Various authors have used the distance to the $k(n)^{th}$ nearest neighbor as the window instead, thus making the choice of the window data dependent. Such estimators are referred to in the literature as the nearest neighbor estimators. These are the estimators of main interest in this thesis and are discussed fully in the next chapter. The remainder of the thesis is concerned with developing two new nearest neighbor estimators, proving their theoretical properties, and comparing their performance by a Monte Carlo simulation study.
2. THEORETICAL RESULTS

2.1. Introduction

Let $X_1, X_2, ..., X_n$ be a random sample, each identically and independently distributed as the random variable $X$, with unknown density function $f(\cdot)$. In Section 2.2 we review some of the available kernel estimators of the function $f$. For the case when the function $f$ is to be estimated at a particular point, say $x$, we propose the nearest neighbors estimator $\hat{f}_n(x)$ of $f(x)$, in Section 2.3 and develop consistency results for this estimator. When $f$ is to be estimated over its entire range, we propose the spheres of influence estimator, $\hat{f}_n(\cdot)$, in Section 2.4 and develop its theoretical properties; Section 2.5 is devoted to some concluding remarks.

2.2. Kernel Density Estimators

A method which is often used to estimate probability densities of unknown functional form is the histogram. Let $X_1, X_2, ..., X_n$ be a random sample from an unknown absolutely continuous probability density with domain of positivity $[a, b]$. If the unknown density has an infinite range, we estimate the truncated density on $[a, b]$ only. We assume that the sample points all lie in the interval $[a, b]$.

Partition $[a, b]$ by $a = a_0 < a_1 < ... < a_m = b$. Consider an estimator $f_H$ of the form
\[ f_H(x) = c_i \text{ for } a_i \leq x < a_{i+1}, \quad i = 0,1,...,m-1 \]
\[ f_H(b) = c_{m-1} \]
\[ f_H(x) = 0 \text{ for } x \not\in [a,b], \]

where
\[ f_H(x) \geq 0 \quad \text{and} \quad \int_a^b f_H(x) \, dx = 1. \]

Defining \( q_i \) to be the number of observations falling in the \( i^{\text{th}} \) interval, then the histogram estimator, \( f_H(x) \), is obtained by letting
\[ c_i = \frac{q_i}{n(a_{i+1}-a_i)}, \quad i = 0,1,...,m-1. \]

The intuitive appeal of \( f_H(x) \) is clear. As \( f \) is assumed to be absolutely continuous, if \( a_{i+1}-a_i \) is small,
\[ f(x) \approx f(a_i) \text{ for } a_i \leq x < a_{i+1}, \quad (2.2.2) \]
and hence \( \frac{q_i}{n} \) estimates \( (a_{i+1}-a_i)f(x) \). It can be shown that among estimators of the form (2.2.1), \( \hat{f}_H \) uniquely maximizes the likelihood (Tapia and Thompson, 1978, p. 45),
\[ L(a_0,a_1,...,a_m) = \prod_{j=1}^{n} f(X_j). \]
Most of the time, the partition \( a_0,a_1,...,a_m \) is taken to be equally spaced, say of length \( 2h_n \). If
(i) \( f \) has continuous derivatives up to order three except at the endpoints of \([a, b]\),
(ii) \( f \) is bounded on \([a, b]\) and
(iii) \( h_n \to 0, \; nh_n \to \infty \) and \( n \to \infty \), then for \( x \in [a, b]\),

\[
\text{MSE}(\hat{f}_H(x)) = E[(\hat{f}_H(x) - f(x))^2] \to 0 \text{ as } n \to \infty,
\]
i.e., \( \hat{f}_H(x) \) is a consistent estimator for \( f(x) \), (Tapia and Thompson, 1978, pp. 46-48). By a proper choice of \( h_n \), which depends upon the unknown density \( f(x) \), the global measure, integrated mean square error,

\[
\text{IMSE} = \int \text{MSE}(\hat{f}_H(x)) \, dx
\]
can be made to decrease at the rate of \( n^{-2/3} \).

The histogram suffers a number of drawbacks; namely, the arbitrariness in choosing the size, number and location of the intervals. However, it is a good tool in preliminary data analysis.

Rosenblatt (1956), in a very insightful paper, extended the histogram estimator of a probability density. Assuming the unknown density \( f \) to be continuous, the Rosenblatt estimator is given by

\[
\hat{f}_n(x) = \frac{\# \text{ of sample points in } (x-h_n, x+h_n)}{2nh_n}
\]
where \( h_n \) is a real valued number constant for each \( n \). \( \hat{f}_n(x) \) can also be written as
\[ \hat{f}_n(x) = \frac{F_n(x+h_n) - F_n(x-h_n)}{2h_n} \]

where

\[ F_n(x) = \frac{\# \text{ of sample points } \leq x}{n} \]

If \( h_n \to 0 \) and \( nh_n \to \infty \) as \( n \to \infty \), then it can be shown that the MSE(\( \hat{f}_n(x) \)) \( \to 0 \) as \( n \to \infty \). If \( h_n \) can be chosen to minimize the MSE(\( \hat{f}_n(x) \)), which then depends upon the unknown density \( f \), the rate of convergence of MSE(\( \hat{f}_n(x) \)) is seen to be of the order of \( n^{-4/5} \). Studies of various measures of consistency of density estimators are given in Bickel and Rosenblatt (1973), Kim and Van Ryzin (1974), Nadaraya (1965), Schuster (1970), Van Ryzin (1969), and Woodroofe (1970).

Rosenblatt estimator is essentially a histogram which, for estimating the density at \( x \), say, has been shifted so that \( x \) lies at the center of one of the partition intervals. For estimating the density at another point, the mesh is shifted again so as to make that point, the midpoint of one of the mesh intervals. This shifted histogram estimator can also be written as

\[ \hat{f}_n(x) = \frac{1}{n} \sum_{j=1}^{n} \frac{1}{h_n} K\left( \frac{x-X_j}{h_n} \right) \]  

where

\[ K(u) = \begin{cases} 
\frac{1}{2} & \text{if } |u| < 1 \\
0 & \text{if } |u| \geq 1 
\end{cases} \]
and \( \{X_j\} \) are the data points. Rosenblatt suggested generalizing the above representation to use other functions \( K(\cdot) \), the detailed derivation of the kernel estimators, however, is due to Parzen (1962). He considered kernels of the form

\[
\int_{-\infty}^{\infty} |K(y)| \, dy < \infty,
\]

\[
\sup_{-\infty < y < \infty} |K(y)| < \infty,
\]

\[
\lim_{y \to \infty} |yK(y)| = 0,
\]

\[ K(y) > 0 \]

and

\[
\int_{-\infty}^{\infty} K(y) \, dy = 1.
\]

If \( f \) is assumed to be continuous, then \( \hat{f}_n(x) \) can be shown to be limiting unbiased and consistent under the usual conditions that

\[ h_n \to 0 \quad \text{as} \quad n \to \infty \]

and

\[ nh_n \to \infty \quad \text{as} \quad n \to \infty. \]

The rate of convergence of the mean squared error at some point \( x \) or the integrated mean squared error is of the order of \( n^{-4/5} \), the same as the one obtained for the shifted histogram, if \( h_n \) is chosen to minimize MSE(\( x \)) or IMSE, respectively. Note that \( h_n \) then depends upon the unknown
density $f(\cdot)$.

The problem of determining the sequence \{$h_n$\} to achieve best results is not answered in the absence of the knowledge about the unknown density $f(\cdot)$. Various authors have tried to answer this question in one manner or another, e.g., Silverman (1978b), Schuster and Gregory (1978). However, the estimate is still not satisfactory. Moreover, if the density $f$ is very low in some region and if only one sample point falls in that region, then the kernel estimator will have a peak at that sample point and be too low over the remainder of that region. Similarly, in the region where $f$ is large, the sample points are more densely packed together and the kernel estimator will tend to spread out the high density region. To overcome these drawbacks, kernel density estimators with variable windows were developed.

Loftsgaarden and Quesenberry (1965) studied an estimator $g_n(x)$ which is the ratio of the empiric measure and the Lebesgue measure of the sphere $S_k(x)$ centered at $x$ and having radius $R(k,x)$ equal to the distance from $x$ to the $k(n)$th nearest of $X_1,X_2,\ldots,X_n$. \={$k(n)$\} is a sequence of positive integers such that

$$\lim_{n \to \infty} k(n) = \infty$$

and

$$\lim_{n \to \infty} \frac{k(n)}{n} = 0.$$

In the univariate case,

\[ g_n = \frac{\# \text{ of points in } (x-R(k,x), x+R(k,x))}{2R(k,x)} \]

Loftsgaarden and Quesenberry showed that \( g_n \) is pointwise consistent in probability at continuity points of \( f \). Estimators utilizing the distance to the \( k(n)^{th} \) nearest neighbor are denoted in the literature as the nearest neighbor estimators. Wagner (1973) established pointwise consistency with probability one under an additional assumption equivalent to

\[ \lim_{n \to \infty} \frac{k(n)}{\log n} = \infty \quad (2.2.4) \]

In fact, Moore and Yackel (1977a,b) point out that \( g_n \) is pointwise consistent with probability one under the weaker condition that

\[ \lim_{n \to \infty} \frac{k(n)}{\log \log(n)} = \infty \]

and show that this condition is the weakest possible. Moore and Henrichon (1969) prove uniform consistency with probability one of \( g_n \) in the univariate case under the condition that (2.2.4) holds. A general nearest neighbor density estimator, Moore and Yackel (1977a), is defined as

\[ f_n(x) = \frac{1}{nR(k,x)P} \sum_{j=1}^{n} K(\frac{x-x_i}{R(k,x)}) \]
where \((X_1, X_2, \ldots, X_n)\) is a random sample from a \(p\)-variate distribution with unknown probability density function \(f\). They show that any consistency theorem true for the bandwidth estimator using kernel \(K\) and also true for the uniform kernel, remains true for \(f_n\) also. Wagner (1975) studied a similar estimator which replaces \(R(k, x)\) with a random radius \(\tau_n\) independent of \(x\) and showed pointwise consistency in probability at all continuity points of \(f\). Moore and Yackel's results allow almost all the results available for the bandwidth estimator, i.e., fixed window estimators, to be transferred to the nearest neighbor estimators. However, they leave the question of the choice of the sequence \(\{k(n)\}\) unanswered. Schuster and Gregory (1978) and Breiman, Meisel and Purcell (1977) suggest ways of obtaining \(k(n)\) for practical situations. However, it involves a lot of computations.

Let us examine how Parzen's (bandwidth) kernel estimators and the nearest neighbor estimators tend to estimate the unknown density at some point, say \(x\). When the kernel used is the uniform kernel, the bandwidth estimator takes an interval of fixed length around \(x\), and counts the number of sample points falling in it; i.e.,

\[
\hat{f}_n(x) = \frac{\text{# of sample points in } (x-h_n, x+h_n)}{2nh_n}
\]
So, the interval is fixed, whereas the random number of points falling in it leads to an estimate of $f(x)$. Using the uniform kernel, the nearest neighbor estimator is given by

$$
\hat{g}_n(x) = \frac{k(n)}{n \mu(R(k,x))}
$$

where $\mu(R(k,x))$ is the Lebesgue measure of the sphere of radius $R(k,x)$ around $x$, $R(k,x)$ being the distance from $x$ to its $k(n)^{th}$ nearest neighbor in $X_1, X_2, \ldots, X_n$. In this case, the randomness is provided by the distance to the $k(n)^{th}$ nearest neighbor of $x$. Combining these two ideas, so as to have a random interval around $x$ and a random number of points falling in this interval, both being determined by the sample, leads us to our estimators:

(i) the nearest neighbors estimator, which is studied in Section 2.3, and

(ii) the spheres of influence estimator which is studied in Section 2.4.

2.3. Nearest Neighbors Estimator

Let $X_1, X_2, \ldots, X_n$ be a random sample of size $n$ from a distribution with unknown, continuous and bounded density $f$. It is desired to estimate the density at a point $x$. Let $K$ be a Borel function satisfying:
$K(y) \geq 0$ for all $y$

$$\int_{-\infty}^{\infty} K(y) \, dy = 1$$

$$\sup_{-\infty < y < \infty} |K(y)| < \infty \quad (2.3.1)$$

$$\lim_{y \to \infty} |yK(y)| = 0.$$ 

$K$ is called a kernel. Let $\{k(n)\}$ be a sequence of positive integers such that

$$k(n) = [n^{a'}], \quad 0 < a' < 1$$

Define

$$h_n(x) = \gamma \sum_{j \text{ ranging over } k(n) \text{ nearest neighbors of } x} |x - X_j| \quad (2.3.2)$$

where $\gamma > 0$ is a constant. The nearest neighbors estimator of $f(x)$ is defined to be

$$f_n(x) = \frac{1}{n} \sum_{i=1}^{n} \frac{1}{h_n(x)} K\left(\frac{x - X_i}{h_n(x)}\right).$$

This estimator is similar to the nearest neighbor estimator discussed in the previous section except the window defined by (2.3.2) considers all neighbors up to and including the $k(n)\text{th}$ nearest neighbor whereas only the $k(n)\text{th}$ neighbor was considered before. The motivation behind varying window estimators is that the size of the window at a particular point should be proportional to the denseness of the sample.
around that point. Moreover, the sample points are clustered around the point in question, a smaller window would result in higher weights being given to those points in the estimate reflecting the higher density in the region. The nearest neighbor estimators achieve this by considering the distance to the $k(n)^{th}$ nearest neighbor as the window at a particular point. However, a better measure of the denseness of the sample would be obtained if all the neighbors up to $k(n)$ are utilized. The nearest neighbors estimator achieves this by considering the sum of the distances to each of the neighbors up to $k(n)$ and taking the window proportional to this quantity.

To establish consistency results for $f_n(x)$, we need the following lemmas.

**Lemma 2.3.1:** Let $K$ be a Borel function satisfying:

$$\int_{-\infty}^{\infty} K(y) \, dy < \infty$$

$$\sup_{-\infty < y < \infty} |K(y)| < \infty$$

and

$$\lim_{y \to \infty} y|K(y)| = 0.$$  

Let $g \in L^{1}$, i.e., $\int |g(y)| \, dy < \infty$ and let

$$g_n(x) = \frac{1}{h_n(x)} \int \frac{y}{h_n(x)} K\left(\frac{y}{h_n(x)}\right) g(x-y) \, dy$$

where $\{h_n(x)\}$ is a sequence of positive constants having

$$\lim_{n \to \infty} h_n(x) = 0.$$
for each $x$.

If $x$ is a point of continuity of $g$, then

$$\lim_{n \to \infty} g_n(x) = g(x) \int_{-\infty}^{\infty} K(y) dy.$$ 

Proof: Consider

$$|g_n(x) - g(x)| \int_{-\infty}^{\infty} K(y) dy = \left| \int_{-\infty}^{\infty} K\left(\frac{y}{h_n(x)}\right) g(x-y) \frac{1}{h_n(x)} dy - \int_{-\infty}^{\infty} K\left(\frac{y}{h_n(x)}\right) g(x) \frac{1}{h_n(x)} dy \right|$$

$$= \left| \int_{-\infty}^{\infty} K\left(\frac{y}{h_n(x)}\right) \frac{1}{h_n(x)} \{g(x-y) - g(x)\} dy \right|$$

$$\leq \int_{|y| \leq \delta} |g(x-y) - g(x)| \frac{1}{h_n(x)} K\left(\frac{y}{h_n(x)}\right) dy + \int_{|y| > \delta} |g(x-y) - g(x)| \frac{1}{h_n(x)} K\left(\frac{y}{h_n(x)}\right) dy$$

$$\leq \sup_{|y| \leq \delta} |g(x-y) - g(x)| \cdot \int_{-\infty}^{\infty} |K(z)| dz$$

$$+ \int_{|y| > \delta} \left| \frac{g(x-y)}{y} \frac{y}{h_n(x)} K\left(\frac{y}{h_n(x)}\right) \right| dy$$

$$+ |g(x)| \int_{|y| > \delta} \left| \frac{1}{h_n(x)} K\left(\frac{y}{h_n(x)}\right) \right| dy$$

$$\leq \sup_{|y| \leq \delta} |g(x-y) - g(x)| \int_{-\infty}^{\infty} |K(z)| dz$$

$$+ \frac{1}{\delta} \sup_{|z| > \delta} |zK(z)| \cdot \int_{-\infty}^{\infty} |g(y)| dy$$

$$+ |g(x)| \int_{|z| > \delta} |K(z)| dz$$

$$|z| > \frac{\delta}{h_n(x)}$$

$$|z| > \frac{\delta}{h_n(z)}$$
As $g$ is continuous at $x$, one can take $\delta$ small enough so that

$$\sup_{|y| < \delta} |g(x-y) - g(x)| < \frac{\varepsilon}{3},$$

and

$$\int_{-\infty}^{\infty} |K(z)|\,dz \text{ being finite. Therefore, the first term on the right hand side can be made } \frac{\varepsilon}{3}. \text{ Also, because }$$

$$\lim_{y \to \infty} |yK(y)| = 0, \text{ and } \sup_{|z| > \frac{\delta}{h_n(x)}} |zK(z)| \text{ gets smaller and smaller as } n \to \infty, \text{ and } h_n(x) \to 0. \text{ Since } g \in L^1, \text{ the second term on the right hand side can be made } \frac{\varepsilon}{3} \text{ for large enough } n.$$ 

Lastly, since $\int_{-\infty}^{\infty} |K(y)|\,dy < \infty$, the third term on the right hand side can be made smaller than $\frac{\varepsilon}{3}$. For large enough $n$. Hence, for all $\varepsilon > 0$, there exists $M$ such that for all $n > M$,

$$|g_n(x) - g(x)| \int_{-\infty}^{\infty} K(y)\,dy < \frac{\varepsilon}{3} + \frac{\varepsilon}{3} + \frac{\varepsilon}{3} = \varepsilon.$$

**Lemma 2.3.2:** Let $X_1, X_2, \ldots, X_n$ be independent and identically distributed as

$$X_i = \begin{cases} 
1 \text{ with probability } p \\
0 \text{ with probability } 1-p,
\end{cases}$$

then
\[ e^{-nX} \geq \begin{cases} 
\frac{1}{n} \sum_{i=1}^{n} X_i \geq d; & l > d > p \\
\frac{1}{n} \sum_{i=1}^{n} X_i \leq d; & 0 < d < p 
\end{cases} \]

where

\[ X = -d \ln p - (1-d)\ln(1-p) + d \ln d + (1-d)\ln(1-d) \]  

(2.3.3)

**Proof**: Using the methods of Chernoff (1952), Wozencraft and Jacobs (1965) have derived the Chernoff bound as follows:

If \( X_1, X_2, ..., X_n \) are independently and identically distributed with unknown mean \( \mu \), then

\[ \lambda_0(X-\mu)^n \geq \begin{cases} 
\frac{1}{n} \sum_{i=1}^{n} X_i \geq d; & d > \mu \\
\frac{1}{n} \sum_{i=1}^{n} X_i \leq d; & d < \mu 
\end{cases} \]  

(2.3.4)

with \( \lambda_0 \) defined implicitly by

\[ \frac{\lambda_0 X}{\lambda_0 X} = d. \]  

(2.3.5)

Therefore, in our case,

\[ \frac{\lambda_0 X}{\lambda_0 X} = (1-p) + pe_0 \]  

and

\[ \frac{\lambda_0 X}{\lambda_0 X} = pe_0. \]  

(2.3.6)
So, for $0 < d < 1$, by (2.3.5) and (2.3.6)

$$ d = \frac{\lambda_0}{pe(1-p) + pe^{\lambda_0}} $$

giving

$$ \lambda_0 = \ln \left[ \frac{d(1-p)}{p(1-d)} \right] $$

Now,

$$ E(e^{\lambda_0(X-d)}) = e^{\lambda_0 d} E(e^{\lambda_0 X}) $$

$$ = e^{\lambda_0 d \left[ (1-p) + pe^{\lambda_0} \right]} $$

$$ = \left[ \frac{p(1-d)}{d(1-p)} \right]^d \left[ (1-p) + p \frac{d(1-p)}{p(1-d)} \right] $$

$$ = (d) \frac{d}{1-d} \frac{l-p}{1-d} $$

Substituting in (2.3.4) we get the desired result.

Note that, from (2.3.3),

$$ X = T_p(d) - H(d) $$

where

$$ T_p(\alpha) = -\alpha \ln p - (1-\alpha)\ln(1-p) $$

and

$$ H(\alpha) = -\alpha \ln \alpha - (1-\alpha)\ln(1-\alpha) $$

$T_p(\alpha)$ is a linear function of $\alpha$ and $H(\alpha)$ increases from 0 to $\ln 2$ at $\alpha = .5$, and decreases to 0 again at $\alpha = 1$ as shown in Figure 2.1. $T_p(\alpha)$ is tangent to the surface at $\alpha = p$ and
X is as shown in Figure 2.1.

Figure 2.1. Function $H(\alpha)$ and $T_p(\alpha)$

Notice that X increases as $|d-p|$ increases.
Lemma 2.3.3: Let \( X_1, X_2, \ldots, X_n \) be a random sample from a continuous distribution with unknown bounded density function \( f \).

Let
\[
  k(n) = [n^{a'}], \quad 0 < a' < 1,
\]

\[
h_n(x) = \sum_{\ell} |x - X_{\ell}|,
\]

where \( \ell \) ranges over \( k(n) \) nearest neighbors of \( x \) in \( (X_1, \ldots, X_n) \).

\( f(x) > 0, \)

\[
h_n^j = h_n(X_j), \quad j = 1, 2, \ldots, n,
\]

and \( h_n \) is selected at random from \( \{h_n^j\}, j = 1, 2, \ldots, n \), then

(a) for \( 0 < a' < \frac{1}{2} \),

\[
h_n \to 0 \quad \text{in probability}
\]

and \( h_n(x) \to 0 \) with probability 1;

and

(b) \( n^{\alpha'} h_n \to \infty \) in probability for \( 1 - a' < \alpha \);

and \( n^{\alpha'} h_n(x) \to \infty \) with probability 1

for \( 1 - a' < \alpha \).
Proof: Consider $h^*_n(x) = \text{distance from } x \text{ to the } k(n)^{th} \text{ nearest neighbor in } (X_1, \ldots, X_n)$. 

Then for any positive $\delta$,

$$P(n^{\delta}h^*_n(x) > \delta) = P(h^*_n(x) > \delta_n)$$

where $\delta_n = \frac{\delta}{n^{\delta}}$

$$= P(\text{sphere } S \text{ of radius } \delta_n \text{ around } x \text{ contains at most } k(n)-1 \text{ number of points in a sample of size } n \text{ drawn at random})$$

$$= \sum_{j=0}^{k(n)-1} \binom{n}{j} (P(S_{\delta_n}(x)))^j (1-P(S_{\delta_n}(x)))^{n-j}$$

where

$$P(S_{\delta_n}(x)) = \int_{S_{\delta_n}(x)} f(x') dx'$$

$$= \int_{(x-\frac{\delta_n}{2}, x + \frac{\delta_n}{2})} f(x') dx'$$

$$= O(\delta_n^2) = O\left(\frac{1}{n^{\delta}}\right) \quad (2.3.8)$$

Therefore,

$$P(n^{\delta}h^*_n(x) > \delta) = P\left(\sum_{i=1}^{n} \frac{Y_i}{n} \leq \frac{k(n)-1}{n}\right)$$

$$= P\left(\frac{1}{n} \sum_{i=1}^{n} Y_i \leq d_n\right)$$
where \(Y_1, \ldots, Y_n\) are independent identically distributed random variables with probability \(p_n = P(S_{\delta_n}(x))\) and 
\[
d_n = \frac{k(n) - 1}{n}. \quad \text{Now,}
\]
\[
d_n = \frac{n_{\alpha'} - 1}{n} = o\left(\frac{1}{n^{1-\alpha'}}\right)
\]
(2.3.9)

From (2.3.8) and (2.3.9), for \(\beta < 1 - \alpha'\), \(d_n\) is less than \(p_n\) for large enough \(n\) and hence appealing to Lemma 2.3.2, it can be shown that for \(x\) such that \(P(S_{\delta_n}(x)) > 0\),
\[
P(n^{\beta}h_n(x) \geq \delta) \leq e^{-nc} \quad \text{for all} \quad n \geq M,
\]
for some positive constant \(M\). Hence, by Borel-Cantelli lemma,
\[
n^{\beta}h_n(x) \to 0 \quad \text{with probability 1 as} \quad n \to \infty \quad \text{for} \quad \beta < 1 - \alpha'. \quad \text{Now,}
\]
\(\alpha'\) being less than \(1/2\), the condition \(\beta < 1 - \alpha'\) can be satisfied by \(\beta > \alpha'\) also.

Therefore, from (2.3.7), we have that
\[
h_n(x) \leq k(n)h_n^*(x) = n^{\alpha'}h_n^*(x).
\]
And, as \(n^{\alpha'}h_n^*(x) \to 0\) with probability 1, so does \(h_n(x)\).

Now,
\[
P(h_n \geq \delta) = \int P(h_n(x) \geq \delta) f(x) dx.
\]
\(P(h_n(x) \geq \delta)\) is bounded by 1; for each \(x\) for which \(P(S_{\delta}(x)) > 0\), it tends to zero with probability 1; and \(\{x: P(S_{\delta}(x)) > 0\}\) has measure one with respect to \(f\). Therefore, the Lebesgue dominated convergence theorem,
\[
\lim_{n \to \infty} P(h_n > \delta) = 0 \quad \text{for each } \delta > 0.
\]

This implies that \( h_n \to 0 \) in probability, thus proving (a).

To prove (b), it suffices to consider only the \( k(n) \)th nearest neighbor in the definition of \( h_n(x) \). Now, consider \( M > 0 \), then

\[
P(n^{a}h_n(x) \leq M) = P(h_n(x) \leq \frac{M}{n^{a}})
\]

\[
= \sum_{k(n)} \binom{n}{j} (P(S_{\delta_n}(x)))^j (1 - P(S_{\delta_n}(x)))^{n-j},
\]

as the event \( \{x : h_n(x) \leq \frac{M}{n^{a}} \} \) is equivalent to saying that a sphere of radius \( \delta_n = \frac{M}{n^{a}} \) around \( x \) should contain at least \( k(n) \) points. Therefore,

\[
P(n^{a}h_n(x) \leq M) = P\left(\frac{1}{n} \sum_{i=1}^{n} Y_i > k(n) \right),
\]

\( \{Y_i\} \) being independent identically distributed Bernoulli variables with probability \( P(S_{\delta_n}(x)) \). Now,

\[
P(S_{\delta_n}(x)) = \int f(x') \, dx'
\]

\[
(x - \frac{M}{2n^{a}}, x + \frac{M}{2n^{a}})
\]

\[
= 0 \left( \frac{1}{n^{a}} \right) \quad \text{and}
\]

\[
\frac{k(n)}{n} = \frac{1}{n^{1-a'}}, \quad \text{hence for } 1-a' < a < 1,
\]

the conditions of Lemma 2.3.2 are satisfied and it can be shown that
\[ P(n^\alpha h_n(x) \leq M) \leq e^{-nc} \text{ for all } n \geq N, \]
a positive integer. This implies, by the Borel-Cantelli lemma, that \( n^\alpha h_n(x) \to \infty \) with probability one for \( 1-\alpha' < \alpha < 1 \).

Also, by the Lebesgue dominated convergence theorem, \( n^\alpha h_n \to \infty \) in probability. Note that the restriction \( \alpha > 1-\alpha' \) in (b) will yield a value of \( \alpha < \frac{1}{2} \) only if \( \alpha' \) is \( > \frac{1}{2} \). However, for (a) to hold, \( \alpha' \) has to be \( < \frac{1}{2} \). A slight modification will do the trick.

Let \( k(n) = \lfloor n^{1/2} \rfloor + 1 \), then \( k(n) = n^{\alpha'} \), for a value of \( \alpha' > \frac{1}{2} \). Also, as (a) holds true when \( \lfloor n^{1/2} \rfloor \) neighbors are considered and when \( k(n) \) nearest neighbor is considered by itself, it holds true when \( k(n) \) nearest neighbors are considered too. Hence, we have a value of \( \alpha' > \frac{1}{2} \) for which (a) holds. Now, we shall state and prove consistency results for the nearest neighbors estimator, \( f_n(x) \).

**Theorem 2.3.1:** Let \( K \) be the uniform density on \([-1,1]\) and let \( h_n(x) \) satisfy

(a) \( h_n(x) \to 0 \) as \( n \) tends to \( \infty \) with probability 1, and

(b) \( n^\alpha h_n(x) \to \infty \) as \( n \) tends to \( \infty \) for some \( 0 < \alpha < \frac{1}{2} \),

then

(i) at every continuity point of \( f \), \( f_n(x) \to f(x) \) with probability 1, and

(ii) if \( f \) is uniformly continuous on \( \mathbb{R} \), and

\[ n^\alpha \inf_x h_n(x) \to \infty \] with probability 1 for some \( 0 < \alpha < \frac{1}{2} \),
then
\[
\sup_x |f_n(x) - f(x)| \to 0 \text{ with probability } 1.
\]

**Proof:** Consider
\[
f_n(x) = \frac{1}{n} \sum_{i=1}^{n} \frac{1}{h_n(x)} K\left(\frac{x-X_i}{h_n(x)}\right),
\]
where
\[
K(x) = \begin{cases} 
\frac{1}{2}, & |x| \leq 1 \\
0, & |x| > 1
\end{cases}
\]

Let
\[
S = \{j : |x-X_j| < h_n(x)\}.
\]

Then
\[
f_n(x) = \frac{1}{2nh_n(x)} \sum_{i \in S} 1
\]

and
\[
|f_n(x) - f(x)| = \frac{1}{n} \sum_{i \in S} 1 - 2h_n(x)f(x) |/2h_n(x)
\]
\[
= \left| \frac{1}{n} \sum_{i \in S} 1 - \int_{x-h_n(x)}^{x+h_n(x)} f(x') dx' \right|
\]
\[
- 2h_n(x)f(x) |/2h_n(x)
\]
\[
\leq \frac{1}{2h_n(x)} \left| \frac{1}{n} \sum_{i \in S} 1 - \int_{x-h_n(x)}^{x+h_n(x)} f(x') dx' \right|
\]
\[
+ \frac{1}{2h_n(x)} \left| \int_{x-h_n(x)}^{x+h_n(x)} f(x') dx' - 2h_n(x)f(x) \right|
\]
(2.3.10)
If $f$ is continuous at $x$, then the second term on the right hand side of (2.3.10) converges to zero with probability 1 if $h_n(x) \to 0$ with probability 1. Let

$$F_n(x) = \frac{1}{n} \{ \# \text{ of points } \leq x \}.$$ 

Hence, the first term in (2.3.10) is

$$= \frac{1}{2h_n(x)} |F_n(x+h_n(x)) - F_n(x-h_n(x)) - F(x+h_n(x)) + F(x-h_n(x))|,$$

where $F$ is the distribution function associated with $f$.

Therefore, it is

$$\sup_x |F_n(x) - F(x)| \leq \frac{\sup_x |F_n(x) - F(x)|}{n^\alpha h_n(x)} \leq \frac{\sup_x |F(x)|}{n^\alpha h_n(x)} \leq \frac{\sup_x |F(x)|}{n^\alpha h_n(x)} = \frac{x}{n^\alpha h_n(x)} \tag{2.3.11}$$

Now, $n^\alpha \sup_x |F_n(x) - F(x)| \to 0$ with probability 1 for $0 < \alpha < \frac{1}{2}$, Keifer and Wolfowitz (1958). Also, by the conditions of the theorem, $n^\alpha h_n(x) \to \infty$ with probability 1 for some $0 < \alpha < \frac{1}{2}$. Therefore, both the terms in (2.3.10) converge to zero with probability 1 and hence $|f_n(x) - f(x)| \to 0$ with probability 1 for $x$ a continuity point of $f$. This proves (i). To prove (ii), note that from (2.3.10) and (2.3.11),
If $f$ is uniformly continuous, then the second term in (2.3.12) tends to zero with probability 1 as $h_n(x) \to 0$ with probability 1 for all $x$. The first term in (2.3.12) tends to zero with probability 1 if $n^\alpha \inf_x h_n(x) \to \infty$ with probability 1 for some $0<\alpha<\frac{1}{2}$, which then proves (ii).

Note that by Lemma 2.3.3, $a'$ and $a$ can be chosen so as to satisfy the conditions of the theorem.

**Theorem 2.3.2:** If the kernel $K$ has bounded variation, and $h_n(x)$ satisfies:

(a) $h_n(x) \to 0$ w.p. 1 for some $0<\alpha<\frac{1}{2}$, and

(b) $n^\alpha h_n(x) \to \infty$ for some $0<\alpha<\frac{1}{2}$, then

(i) at every continuity point of $f$, $f_n(x) \to f(x)$ w.p.1

(ii) if $n^\alpha \inf_x h_n(x) \to \infty$ w.p. 1 for some $0<\alpha<\frac{1}{2}$, and $f$ is uniformly continuous, then

$$\sup_x |f_n(x) - f(x)| \to 0 \text{ w.p. 1}$$
Proof: \[ |f_n(x) - f(x)| = \frac{1}{h_n(x)} \sum_{i=1}^{n} K_h \frac{x - X_i}{h_n(x)} - f(x) \]

\[ = \left| \frac{1}{h_n(x)} \int K_h \frac{x - y}{h_n(x)} dF_n(y) - f(x) \right| \]

\[ = \left| \frac{1}{h_n(x)} \int K_h \frac{x - y}{h_n(x)} dF_n(y) - \frac{1}{h_n(x)} \int K_h \frac{x - y}{h_n(x)} dF(y) + \frac{1}{h_n(x)} \int K_h \frac{x - y}{h_n(x)} dF(y) - f(x) \right| \]

\[ \leq \frac{1}{h_n(x)} \left| \int K_h \frac{x - y}{h_n(x)} dF_n(y) - \int K_h \frac{x - y}{h_n(x)} dF(y) \right| + \frac{1}{h_n(x)} \int K_h \frac{x - y}{h_n(x)} dF(y) - f(x) \right| \]

Integrating by parts we see that the first term is

\[ \leq \frac{1}{h_n(x)} \int |F_n(y) - F(y)| dK_h \frac{x - y}{h_n(x)} \]

\[ \leq \frac{V}{h_n(x)} \sup_y |F_n(y) - F(y)|, \text{ where} \]

V is the total variation of K.

Hence it is \[ \leq \frac{V}{n^\alpha h_n(x)} \sup_y |F_n(y) - F(y)|, \quad 0 < \alpha \leq \frac{1}{2} \]

and \[ n^\alpha \sup_y |F_n(y) - F(y)| \to 0 \] with probability one for \[ 0 < \alpha < \frac{1}{2} \].

Also, if \[ n^\alpha h_n(x) \to \infty \] with probability 1, the first term \[ \to 0 \] with probability 1. Now, the second term in (2.3.13) is equal to

\[ \left| \frac{1}{h_n(x)} \int K_h \frac{x - y}{h_n(x)} f(y) dy - f(x) \right| \]
which →0 by Lemma 2.3.1.

Hence, \( f_n(x) + f(x) \) with probability 1. This proves (i).

To prove (ii), note that

\[
\sup_x |f_n(x) - f(x)| \leq \frac{\sup_y |F_n(y) - F(y)|}{\inf_y h_n(y)}
\]

\[
+ \sup_x \left| \frac{1}{h_n(x)} \int [X - Y] f(y) dy - f(x) \right|
\]

If for some \( 0 < \alpha < \frac{1}{2} \), \( n^\alpha \inf_y h_n(y) \to \infty \) w.p. 1, then the first term →0 w.p. 1. Also, if \( f \) is uniformly continuous, then Nadaraya (1965) has shown that the second term →0 w.p. 1, if \( h_n(x) \to 0 \) w.p. 1. Thus \( \sup_x |f_n(x) - f(x)| \to 0 \) w.p. 1.

Note that \( \alpha' \) and \( \alpha \) can be chosen according to Lemma 2.3.3 to satisfy the conditions of the theorem.

Following the method of Schuster and Gregory (1978), an estimator very similar to the nearest neighbors estimator can be defined as follows.

Divide the sample of size \( n \) into two parts randomly of size \( n_1 \) and \( n_2 \), \( n_1 + n_2 = n \). Let \( X_1,...,X_{n_1} \) and \( Y_1,...,Y_{n_2} \) be the two parts of the original sample.

Define \( h_1(x) = \sum_{j} |x - Y_j| \) \[(2.3.14)\]

j ranging over \( k_1(n) \) nearest neighbors of \( x \) in \( (Y_1,...,Y_{n_2}) \)
and
\[ h_2(x) = \gamma_2 \sum_{j \text{ ranging over } k_2(n) \text{ nearest neighbors}} |x-x_j| \]
of \( x \) in \( (X_1, \ldots, X_{n}) \),
where
\[ k_1(n) = [n^{\alpha'}], \quad 0<\alpha'<1, \]
\[ k_2(n) = [n^{\alpha'}], \quad \text{for some } 0<\alpha'<1, \] and \( \gamma_1, \gamma_2 \) are some positive constants.

Then
\[ \hat{f}_n(x) = \frac{\sum_{i=1}^{n_1} f_{1,n_1}(x) + \sum_{i=1}^{n_2} f_{2,n_2}(x)}{n} \tag{2.3.15} \]
where \( f_{i,n_i}(x) \) is the nearest neighbors estimator, with \( h_i(x) \)
as the window and the ith subsample used with it, \( i = 1,2 \).

Then the results of Theorems 2.3.1 and 2.3.2 hold true for \( \hat{f}_n(x) \)
also, since it is a linear combination of two nearest neighbors estimators. Moreover, it can be shown now that
\( \hat{f}_n(x) \) is limiting unbiased and consistent in mean squared error. This is established in Theorems 2.3.3 and 2.3.4.

**Theorem 2.3.3:** If
(i) \( h_1(x) \) and \( h_2(x) \to 0 \) with probability 1 and
(ii) \( f \) is continuous at \( x \), then
\[ \lim_{n \to \infty} E(\hat{f}_n(x)) = f(x) \] with probability 1, where \( f_n(x) \)
is defined by (2.3.15).
Proof:

\[ E(f_{1,n_1}(x)) = \frac{1}{n_1} \sum_{i=1}^{n_1} \frac{1}{h_1(x)} K\left(\frac{x-x_i}{h_1(x)}\right) \]

\[ = \frac{1}{n_1} \sum_{i=1}^{n_1} \frac{1}{h_1(x)} E\{K\left(\frac{x-x_i}{h_1(x)}\right)\} \]

as \( h_1(x) \) does not depend upon \( X_1, X_2, \ldots, X_{n_1} \) by definition, (2.3.14).

Therefore,

\[ E(f_{1,n_1}(x)) = \frac{1}{n_1} \sum_{i=1}^{n_1} \frac{1}{h_1(x)} \int K\left(\frac{x-x_i}{h_1(x)}\right) f(X_i) dX_i \]

\[ = \int K(y)f(x-h_1(x)y)dy. \quad (2.3.16) \]

By Lemma (2.3.1), (2.3.16) converges to \( f(x)\int_{-\infty}^{\infty} K(y)dy = f(x) \), which implies that

\[ E(f_{1,n_1}(x)) = f(x) + O(h_1(x)). \]

and

\[ E(f_{2,n_2}(x)) = f(x) + O(h_2(x)). \]

Therefore,

\[ \hat{E}_{n}(x) = E\left(\frac{n_1 f_{1,n_1}(x) + n_2 f_{2,n_2}(x)}{n}\right) + f(x) \text{ with probability 1} \]}
Theorem 2.3.4: The estimator \( \hat{f}_n(x) \) defined in (2.3.15) is consistent if

(i) \( h_1(x), h_2(x) \to 0 \) with probability 1,

(ii) \( n_1h_1(x), n_2h_2(x) \to \infty \) with probability 1, and

(iii) \( x \) is a continuity point of \( f \).

Proof: Consider

\[
\text{Var}(f_1,n_1(x)) = \text{Var}\left( \frac{1}{n_1} \sum_{i=1}^{n_1} \frac{1}{h_1(x)} K\left( \frac{x-X_i}{h_1(x)} \right) \right)
\]

\[
= \frac{1}{n_1} \text{Var}\left[ \frac{1}{h_1(x)} K\left( \frac{x-X_i}{h_1(x)} \right) \right]
\]

\[
\leq \frac{1}{n_1} E\left[ \frac{1}{h_1(x)} \int_K \left[1 \left( \frac{x-y}{h_1(x)} \right)^2 f(y) \right] dy \right]
\]

\[
= \frac{1}{n_1 h_1(x)} \int_K \left[1 \left( \frac{x-y}{h_1(x)} \right)^2 f(y) \right] dy
\]

\[
\to 0 \text{ by Lemma (2.3.1)}.
\]

Now,

\[
\text{MSE}(f_1,n_1(x)) = E[|f_1,n_1(x) - f(x)|^2]
\]

\[
= \text{Var}(f_1,n_1(x)) + \text{Bias}^2(f_1,n_1(x))
\]

and by Theorem (2.3.3),

\[
\text{Bias}(f_1,n_1(x)) \to 0 \text{ with probability 1 if } h_1(x) \to 0 \text{ with probability 1 and thus,}
\]

\[
\text{MSE}(f_1,n_1(x)) \to 0 \text{ with probability 1 for } i = 1,2.
\]

And since \( \hat{f}_n(x) \) is a linear combination of \( f_{i,n_i}(x) \),

\[
\text{MSE}(\hat{f}_n(x)) \to 0 \text{ with probability 1.}
\]
Note that conditions of Theorems 2.3.3 and 2.3.4 can be satisfied by choosing \( a' \) and \( a \) according to Lemma 2.3.3.

2.4. Spheres of Influence Estimators

When the density is to be estimated at several points, the computations of windows around each one of them is necessary before the nearest neighbors estimator studied in Section 2.3 can be used. Instead, if each sample point is considered to have a "sphere of influence" in which it contributes to the estimation of density, then only these spheres of influence of each sample point need be computed and used over and over again to estimate the density at any point in the range of the unknown density \( f \). The estimator discussed in this section uses this concept and takes this sphere of influence around each sample point to be proportional to the window at that point.

Let \( X_1, X_2, \ldots, X_n \) be a random sample from a distribution with unknown density, \( f \). Let \( K \) be a Borel function satisfying (2.3.1). Let \( \{k(n)\} \) be a sequence of positive integers, such that

\[
k(n) = \lceil n^{\alpha'} \rceil, \quad 0 < \alpha' < 1
\]

Define

\[
h_{jn} = \gamma \sum_{\ell} |X_j - X_\ell|, \quad j = 1, \ldots, n
\]

(2.4.1)

\( \ell \) ranges over \( k(n) \) neighbors of \( X_j \)
where \( \gamma > 0 \) is a constant.

The spheres of influence estimator is defined as

\[
g_n(\cdot) = \frac{1}{n} \sum_{i=1}^{n} \frac{1}{h_{in}} K\left(\frac{x-X_i}{h_{in}}\right)
\]

Note that

\[
\int g_n(x) dx = \frac{1}{n} \sum_{i=1}^{n} \int \frac{1}{h_{in}} K\left(\frac{x-X_i}{h_{in}}\right) dx = \frac{1}{n} \sum_{i=1}^{n} K(y_i) dy_i = 1
\]

and \( g_n(\cdot) \geq 0 \), so that \( g_n \) is a density. Consider the estimates

\[
f_{jn}(x) = \frac{1}{n} \sum_{i=1}^{n} \frac{1}{h_{jn}} K\left(\frac{x-X_i}{h_{jn}}\right), \quad j = 1, \ldots, n.
\]

By Wagner's results (1975), \( f_{jn}(x), \ j = 1, 2, \ldots, n, \) is a consistent estimator of \( f(x) \) in the sense that \( f_{jn}(x) \rightarrow f(x) \) in probability as \( n \to \infty \) if \( 1-\alpha' < \alpha < 1 \) and \( K \) is of bounded variation. Wagner proved the results for the case when only the \( k(n) \) nearest neighbor is used in (2.4.1) but to extend it to the present situation is similar to the methods employed in Section 2.3.

Therefore, for each \( \epsilon > 0 \),

\[
P(\left| f_{jn}(x) - f(x) \right| \leq \epsilon) \to 1 \text{ as } n \to \infty, \quad j = 1, 2, \ldots, n
\]
i.e., \( P(-\epsilon \leq f_{jn}(x) - f(x) \leq \epsilon) \to 1 \text{ as } n \to \infty, \) which implies that
\begin{align*}
P(-n\varepsilon < \sum_{j=1}^{n} f_{jn}(x) - nf(x) \leq n\varepsilon) & \rightarrow 1 \text{ as } n \to \infty \\
\text{and} \quad -n\varepsilon < \sum_{j=1}^{n} f_{jn}(x) - nf(x) \leq n\varepsilon \tag{2.4.2}
\end{align*}

for all \( n > N_1 \), a positive constant, with probability arbitrarily close to 1.

Now

\begin{align*}
&\sum_{j=1}^{n} f_{jn}(x) - nf(x) \\
&\quad = \sum_{j=1}^{n} \frac{1}{n} \sum_{i=1}^{n} \frac{1}{h_{jn}} K\left(\frac{x-X_i}{h_{jn}}\right) - nf(x) \\
&\quad = \frac{1}{n} \sum_{j=1}^{n} \frac{1}{h_{jn}} K\left(\frac{x-X_j}{h_{jn}}\right) \\
&\quad \quad + \frac{1}{n} \sum_{j \neq i} \frac{1}{h_{jn}} K\left(\frac{x-X_i}{h_{jn}}\right) - nf(x) \\
&\quad = g_n(x) - f(x) + \frac{1}{n} \sum_{j=1}^{n} \sum_{i \neq j} \frac{1}{h_{jn}} K\left(\frac{x-X_i}{h_{jn}}\right) \\
&\quad \quad - (n-1)f(x) \\
&\quad = \{g_n(x) - f(x)\} + (n-1)\left\{\frac{1}{n} \sum_{j=1}^{n} \frac{1}{h_{jn}} \sum_{k \neq j} \frac{1}{h_{jn}} K\left(\frac{x-X_i}{h_{jn}}\right) \right. \\
&\quad \quad \quad \left. - f(x)\right\} \tag{2.4.3}
\end{align*}

Now, for each \( j \),

\begin{align*}
\frac{1}{n-1} \sum_{i \neq j} \frac{1}{h_{jn}} K\left(\frac{x-X_i}{h_{jn}}\right)
\end{align*}
is a consistent estimator of \( f(x) \) and hence their average is also consistent. Therefore, the second term in (2.4.3) converges to zero in probability and hence for the \( \varepsilon > 0 \) chosen before,

\[
(n-1) \left| \frac{1}{n} \sum_{j=1}^{n} \frac{1}{n-1} \sum_{i \neq j} \frac{1}{h_{jn}} K\left(\frac{x-X_i}{h_{jn}}\right) \right| = f(x) \leq (n-1) \varepsilon
\]  

(2.4.4)

for all \( n \geq N_2 \), for some \( N_2 > 0 \), with probability arbitrarily close to 1. Substituting (2.4.4) in (2.4.2), we have

\[
-n \varepsilon \leq \sum_{j=1}^{n} f_{jn}(x) - nf(x) \leq n \varepsilon
\]

if and only if

\[
-n \varepsilon \leq \{g_n(x) - f(x)\} + (n-1) \left\{ \frac{1}{n} \sum_{j=1}^{n} \frac{1}{(n-1)} \sum_{i \neq j} \frac{1}{h_{jn}} K\left(\frac{x-X_i}{h_{jn}}\right) \right\} - f(x) \leq n \varepsilon
\]

Hence, for all \( n \geq \max(N_1, N_2) \),

\[
-n \varepsilon + (n-1) \varepsilon \leq g_n(x) - f(x) \leq n \varepsilon - (n-1) \varepsilon
\]

i.e., \( |g_n(x) - f(x)| \leq \varepsilon \) with probability arbitrarily close to 1. Therefore, Theorems 2.3.1 and 2.3.2 can be carried over to the spheres of influence estimator.
Theorem 2.4.1: Let $K$ be the uniform density on $[-1,1]$ and let $\{h_{jn}\}, j = 1,2,...,n$ satisfy the following conditions:

(a) $h_{jn} \to 0$ in probability, $j = 1,2,...,n$ and

(b) $n^{\alpha}h_{jn} \to \infty$ in probability for some $0 < \alpha < \frac{1}{2}$, $j = 1,2,...,n$.

then

(i) at every continuity point of $f$, $g_{n}(x) \to f(x)$ in probability

(ii) if $f$ is uniformly continuous on $\mathbb{R}$, then

\[
\sup_{x} \|g_{n}(x) - f(x)\| \to 0 \text{ in probability}
\]

Theorem 2.4.2: If the kernel $K$ has bounded variation, and $\{h_{jn}\}, j = 1,2,...,n$, satisfy,

(a) $h_{jn} \to 0$ in probability, $j = 1,2,...,n$

and

(b) $n^{\alpha}h_{jn} \to \infty$ in probability for some $0 < \alpha < \frac{1}{2}$, $j = 1,2,...,n$.

Then,

(i) at every continuity point of $f$, $g_{n}(x) \to f(x)$ in probability, and

(ii) if $f$ is uniformly continuous, then

\[
\sup_{x} \|g_{n}(x) - f(x)\| \to 0 \text{ in probability}.
\]
2.5. Remarks

The nearest neighbors and spheres of influence estimators use the data in determining windows for kernel density estimators in such a way that the windows and the number of points falling in them are both random. In various empirical studies, we have found that the optimal choice of \( k(n) \) lies around \( n^{1/2} \) and that \( k(n) = n^{1/2} \) gives the optimal estimate for all practical purposes. The choice of the constant multiple \( \gamma \) can be determined by a search over a grid of values maximizing the likelihood type function

\[
\prod_{i=1}^{n} \hat{f}_n(x_i), \quad \text{where } \hat{f}_n(x_i) \text{ is the estimate based on the sample with } X_i \text{ removed. The value of } \gamma \text{ is usually close to unity. In the next chapter, we examine various possibilities regarding the choice of } \gamma \text{ and suggest a way of fixing } \gamma.
\]

Results of simulation studies using this technique and comparison with the fixed window kernel estimator using optimal window size are presented in Chapter 3.
3. SIMULATION RESULTS

3.1. Introduction

In the preceding chapter, we have shown that the nearest neighbors and the spheres of influence estimators are consistent estimators of the unknown continuous univariate density $f$. However, the parameters $\alpha'$ and $\gamma$ in the definition of

$$k(n) = [n^{\alpha'}], \quad 0 < \alpha' < 1$$

and

$$h(x) = \gamma \sum |x - x_j|$$

$j$ ranging over $k(n)$

nearest neighbors of $x$ in

$$(X_1, X_2, \ldots, X_n)$$

are yet to be determined before these estimators can be used in practice. It is desirable to have estimators which do not involve constants depending upon the unknown density $f$. A one shot approach which provides an estimate on obtaining a sample of size $n$ is what we hope to achieve.

One method of choosing $(\alpha', \gamma)$ is to use the method suggested by Shuster and Gregory (1978) for the nearest neighbor estimator which utilizes the distance to the $k(n)^{th}$ nearest neighbor in determining the window at a point. They used a grid of values of $(\alpha', \gamma)$ to maximize
\[ \prod_{i=1}^{n} \hat{f}(X_i) \tag{3.1.1} \]

\( \hat{f}(X_i) \) is the estimate at \( X_i \) based on \((n-1)\) observations with \( X_i \) deleted. In test runs with various distributions, the optimal values of \( \alpha' \) and \( \gamma \) for the nearest neighbors and spheres of influence estimators were found to lie around \((.5, 1)\). The use of the optimality criterion (3.1.1) did not give any great improvement in mean squared error and required a large number of computations to implement. Moreover, fixing the values of

\[
\begin{align*}
\alpha' &= .5 \\
\gamma &= 1
\end{align*}
\]

provides a quick and easy method of obtaining density estimates. It is interesting to note that for nearest neighbor estimator which uses only the \( k(n) \)th nearest neighbor to define the window at a point, the optimal value of \( \alpha' \) can generally be as high as \(.8\).

In evaluating nearest neighbors and spheres of influence estimators, the sample has to be sorted in ascending order so that the neighbors of a point can be found. The computations required to sort and then to find neighbors of a point increase rapidly as the sample size increases. This may not be much of a drawback since other methods require specification of some parameters before an estimate of the
density can be obtained. Knowledge about these parameters may not be available and in its absence good estimates will not be possible. However, for a large enough sample size, the naive shifted histogram estimator will yield good estimates and as the computing time required is small, a few test runs with different window sizes will be sufficient. For small sample sizes, say up to 200, the nearest neighbors estimators are superior to the other kernel estimators and provide estimates without any information besides the sample.

In this chapter, we study the mean squared error rates and efficiency comparisons of the nearest neighbors and spheres of influence estimators by generating samples from different distributions. Section 3.2 discusses the distribution considered and the method of comparison, Section 3.3 presents the results of the simulation study and Section 3.4 is devoted to some concluding remarks.

3.2. Method of Comparison

To determine the efficiency of the estimators, the kernel fixed window estimator (2.2.3) is used as a standard. It is defined as

$$\hat{f}_n(x) = \frac{1}{n} \sum_{i=1}^{n} \frac{1}{h_n} K\left(\frac{x-x_i}{h_n}\right)$$
where \( \{h_n\} \) is a sequence of constants, and \( K \) is the kernel used. The integrated mean squared error for this estimator is of the order of \( O(n^{-4/5}) \) and this convergence is fastest when

\[
h_n = n^{-1/5} \alpha(K) \beta(f),
\]

and

\[
\alpha(K) = \left[ \frac{\int K^2(y) dy}{2r(\int y^r K(y) dy / r!)^2} \right]^{1/2r + 1}
\]

and

\[
\beta(f) = \left[ \int |f^{(r)}(y)|^2 dy \right]^{-1/(2r+1)}
\]

Tapia and Thompson (1978). The value \( r \) is called the characteristic exponent of the kernel \( K \) and for the kernels used in this simulation, the value of \( r \) used was 2. Although \( \beta(f) \) is a function of the unknown density, for the purpose of comparing efficiencies we can use the fixed window kernel estimator with the optimal window given by (3.2.1) as a standard technique against which the new estimators are tested.

Three distributions are considered. The normal distribution with mean zero and unit variance; equal mixture of normal distributions with means -1.5 and 1.5 and unit variances; and the t-distribution with 5 degrees of freedom. Three kernels with characteristic exponent \( r=2 \) are used. The uniform kernel \( K_1 \), the quartic kernel \( K_2 \) and the normal kernel \( K_3 \). The values of \( \alpha(K) \) used in the definition of the optimal window, (3.2.1) are presented in Table 3.1. For each of the distributions listed, each of the kernels is used for sample
Table 3.1. Values of $\alpha(K)$

</table>

sizes of 50 and 100. All samples were generated by the random number generators of the IMSL programs. Fifty equidistant points in the range of (-4, 4) for $N(0,1)$ and $t_5$ distributions, and in the range of (-5, 5) for the mixture of two normal distributions, are selected at which the unknown density is estimated. The estimates of mean squared error at these points are obtained by repeating the estimation procedure a hundred times with a new random sample at each repetition.
3.3. Results

For each distribution, kernel and sample size, we present
(i) the integrated mean squared error,
(ii) efficiency of nearest neighbors, and spheres of
 influence estimators compared to the optimal fixed
 window kernel estimator,
(iii) the mean squared errors of the three estimators
 at the fifty points at which the density is
 estimated for a sample size and kernel, and
(iv) a sample plot of the estimates obtained by the
 three methods for a sample size and kernel.

These are given in Tables 3.2, 3.3, 3.4 and Figure 3.1
for the Normal (0,1) distribution, Tables 3.5, 3.6, 3.7,
and Figure 3.2 for the equal mixture of normal distributions,
and in Tables 3.8, 3.9, 3.10 and Figure 3.3 for the t-
distribution with five degrees of freedom.

From the tables, it is seen that the spheres of in-
fluence and nearest neighbors estimators are better than the
fixed optimal window kernel estimator in most instances.
The efficiencies of the estimators for the Normal (0,1)
distribution are between 45 and 105% for the uniform and
quartic kernels but they are between 113 and 137% for the
normal kernel. For estimating the bimodal distribution,
equal mixture of normal distributions, the spheres of in-
fluence and nearest neighbor estimators are superior for the
uniform and normal kernels and the fixed optimum window kernel estimators is only slightly better for the quartic kernel. For estimating the t-distribution, the spheres of influence and nearest neighbor estimators are at least as good or better than the fixed optimal window kernel estimator. Considering that the fixed window estimator uses the optimal window size which is a function of the unknown density \( f \), our estimators are preferable and perform better also.

It is natural to compare these estimators to the nearest neighbor estimator which utilizes only the \( k(n) \)th nearest neighbor of a point in determining the window. However, no efficient algorithm is available to determine the values of \( \alpha' \) and \( \gamma \). Using the values of \( \alpha' = .5 \) and \( \gamma = 1 \) leads to absurd estimates and efficiencies of the order of 400%-800% for the nearest neighbors estimators. The nearest neighbor estimator is sensitive to the choice of \( \alpha' \) and the optimal value is around .8. Also, for the small sample sizes considered, the nearest neighbor estimator is not very superior to the fixed optimal window kernel estimator and hence comparison of our estimators to the fixed window estimator is sufficient for establishing their usefulness and preferability.

The nearest neighbors estimator is more efficient in the region where the density is large compared to the other two estimators. The spheres of influence estimator, though more efficient than the fixed window estimator, is less
efficient than the nearest neighbors estimator in the region where the density is away from zero. In sparse areas, the fixed window estimator is more efficient than the other two and the spheres of influence estimator is more efficient than the nearest neighbors estimator. Among the kernels considered, the quartic and normal kernel gave better results for the fixed window estimator. For estimating the Normal $(0,1)$ distribution, the normal kernel gave better results for our estimators. However, the uniform kernel performed at least as good as the other two considered for estimating the mixture of normals and the t-distribution.

3.4. Conclusions

The nearest neighbors and spheres of influence estimators provide good estimates for small samples from the unknown continuous distribution without the need to supply any parameters before the estimation procedure can be started. These estimators are especially good for densities with long drawn out tail areas. As the nearest neighbors estimator requires computation of neighbors of the points at which the estimates are desired, it can be used when it is desired to estimate the density at a few points only. The spheres of influence estimator lends itself to the situation when the density is to be estimated over the entire range. For large samples, the nearest neighbors estimator is preferable as the
number of neighbors to consider increases at the rate of $n^5$ only.

In this thesis, we have presented a one-shot approach to univariate density estimation which requires only the sample, and its sample size $n$. Further research to extend the results of this thesis to multivariate distributions and finding efficient algorithms to implement them is a further area of research.

4. BIBLIOGRAPHY

5. ACKNOWLEDGMENTS

I would like to express my gratitude to Dr. J. E. Gentle for suggesting this dissertation topic and supervising the research in the initial stages while he was at Iowa State University. I would also like to thank Dr. V. A. Sposito who graciously accepted to be my major professor after Dr. Gentle's departure and painstakingly supervised the final preparation of the dissertation, even after my leaving Ames. I also wish to thank the other committee members, Dr. W. J. Kennedy, Dr. D. H. Harville, Dr. K. J. Koehler and Dr. C. G. Maple for their willingness to serve on the committee.

Thanks are due to the Statistical Numerical Analysis section for the financial support provided while I was at Iowa State University and Schering Corporation for providing computing facilities to complete the simulation study.

Thanks go to my colleagues and friends, Mr. Vaithianathan, Mr. Skarpness and Mr. Escobar for the help they provided in getting the dissertation typed, and completing other formalities.

Finally, thanks are due to my wife and parents for their patience and understanding during my years of graduate study.
