The Role of Dietary Vitamin E in Experimental Listeria monocytogenes Infections in Turkeys

Abstract
The current study was designed to determine if dietary vitamin E influenced either the gut clearance or levels of peripheral blood CD4+ and CD8+ T lymphocytes in adult turkeys experimentally infected with Listeria monocytogenes. Turkeys were fed vitamin E (0, 100, or 200 IU) from day of hatch to time of necropsy. After 6 wk on the experimental diet, turkeys were orally inoculated with L. monocytogenes (∼ 10⁹ cfu). To monitor infection status, cloacal swabs were taken on selected days post-inoculation (DPI). At necropsy, samples of viscera, including liver, spleen, cecum, duodenum, ileum, and colon were collected and cultured for L. monocytogenes. In experiments 1 and 2, recovery of L. monocytogenes from cloacal swabs, tissues, and intestines from turkeys fed vitamin E was generally lower than that from turkeys fed the control diet, although these differences were not statistically significant. When data from both trials were combined, L. monocytogenes was cultured less frequently from cloacal swabs of the vitamin E-treated group (200 IU) on 2 and 3 DPI, when compared to controls (0 IU, P < 0.01). There were no changes in virulence characteristics of L. monocytogenes cells, as measured by in vitro killing of Ped-2E9 cells, recovered from cloacal swabs or tissues of experimentally infected turkeys fed the control or a vitamin E treatment diet. Flow cytometric analysis indicated that CD4+ and CD8+ peripheral blood T lymphocytes were elevated at 6 and 8 DPI in infected turkeys given 200 IU vitamin E.

**ABSTRACT** The current study was designed to determine if dietary vitamin E influenced either the gut clearance or levels of peripheral blood CD4+ and CD8+ T lymphocytes in adult turkeys experimentally infected with *Listeria monocytogenes*. Turkeys were fed vitamin E (0, 100, or 200 IU) from day of hatch to time of necropsy. After 6 wk on the experimental diet, turkeys were orally inoculated with *L. monocytogenes* (∼10⁹ cfu). To monitor infection status, cloacal swabs were taken on selected days post-inoculation (DPI). At necropsy, samples of viscera, including liver, spleen, cecum, duodenum, ileum, and colon were collected and cultured for *L. monocytogenes*. In experiments 1 and 2, recovery of *L. monocytogenes* from cloacal swabs, tissues, and intestines from turkeys fed vitamin E was generally lower than that from turkeys fed the control diet, although these differences were not statistically significant. When data from both trials were combined, *L. monocytogenes* was cultured less frequently from cloacal swabs of the vitamin E-treated group (200 IU) on 2 and 3 DPI, when compared to controls (0 IU, *P* < 0.01). There were no changes in virulence characteristics of *L. monocytogenes* cells, as measured by in vitro killing of Ped-2E9 cells, recovered from cloacal swabs or tissues of experimentally infected turkeys fed the control or a vitamin E treatment diet. Flow cytometric analysis indicated that CD4+ and CD8+ peripheral blood T lymphocytes were elevated at 6 and 8 DPI in infected turkeys given 200 IU vitamin E.

(Key words: CD4+ and CD8+, immune response, *Listeria*, turkey, vitamin E)

2003 Poultry Science 82:1559–1564

**INTRODUCTION**

*Listeria monocytogenes* is a major human bacterial foodborne pathogen that annually accounts for ∼2,500 cases (meningitis, encephalitis, sepsis, fetal death, prematurity) and 504 deaths (Mead et al., 1999). Sporadic human cases of listeriosis have been epidemiologically linked to the consumption of undercooked poultry products (Schwartz et al., 1988). Analysis of risk factors associated with sporadic human listeriosis in the U.S. indicated that cancer patients and immunocompromised patients, in whom 69% of listeriosis cases occur, were more likely than controls to have eaten undercooked poultry (odds ratio = 3.3; Schuchat et al., 1992). A 1998 multistate outbreak of human listeriosis, ascribed to serotype 4 (101 cases, resulting in 22 deaths), was linked to delicatessen meats, including turkey (MMWR, 1998). A 2002 outbreak involving 46 cases, seven deaths, and three stillbirths was linked to contaminated delicatessen turkey meats (MMWR, 2002). The recall of 26 million pounds of turkey meat in 2002 indicates the economic consequences of ready-to-eat meats contaminated with *L. monocytogenes* (U.S. Department of Health and Human Services, 2002).

Adult turkeys may be transiently colonized by consuming contaminated feed or water (Husu et al., 1990). Thus, *L. monocytogenes* may enter the packing plant at low levels in the intestine of recently infected birds, survive in biofilms, and ultimately contribute to both environmental and ready-to-eat product contamination (Genigeorgis et al., 1990; Ojeniyi et al., 1996). In the United States, *L. monocytogenes* was found on 5.9% of turkey carcass rinses and in 31% of ground turkey meat examined in the Nationwide Young Turkey Microbiological Baseline Data Collection Program (U.S. Department of Agriculture, 1998).

Vitamin E is required for normal development and function of the immune system in poultry (Boa-Am-
ponsem et al., 2000; Leshchinsky and Klasing, 2000, 2001). In chickens, vitamin E supplement increased the number of lymphocytes in the bursa and the thymus gland and stimulated the proliferation and differentiation of T cells (Chang et al., 1994). In broilers, vitamin E selectively increased the percentage of mature CD4\(^+\) T helper cells in the thymus and spleen but did not alter the percentage of thymic and splenic B cells and macrophages in total immune cell (Gore and Qureshi, 1997; Erf et al., 1998). Vitamin E enhanced immunity of birds to Escherichia coli infection, coccidiosis, infectious bursal disease, and Newcastle disease and altered cytokine expression in broilers (Tengerdy and Brown, 1977; Colnago et al., 1984; Erf et al., 1998; Leshchinsky and Klasing, 2000). However, vitamin E, although increasing serum levels of α-tocopherol, did not reduce the severity of Eimeria maxima infections in broilers (Allen and Frettener, 2002).

Besides stimulating immune parameters, dietary vitamin E also enhances meat quality. Dietary vitamin E contributes to oxidative stability, extends shelf life and prevents oxidative off-odor of poultry meat, thus preserves the sensory quality of both frozen and refrigerated turkey breast meat (Ahn et al., 1997, 1998; Sheldon et al., 1997).

As part of the immune response during acute listeriosis, the host marshalls neutrophils, macrophages, natural killer cells, and T lymphocytes, especially CD4\(^+\) and CD8\(^+\) cells (Unanue, 2002). In vitro transfer experiments have shown that CD4\(^+\) and CD8\(^+\) cells are required to eliminate infection with wild-type strains of L. monocytogenes in mice (Kaufmann, 1993).

The current study was designed primarily to assess the effectiveness of dietary vitamin E, using doses previously shown to enhance meat quality, in accelerating the gut clearance of L. monocytogenes in experimentally infected adult turkeys. Secondly, we monitored CD4\(^+\) and CD8\(^+\) T lymphocytes to evaluate the role of vitamin E as an immune potentiator.

**MATERIALS AND METHODS**

**Bacterial Inoculum**

_L. monocytogenes_ (ATCC 700301) was obtained from American Type Culture Collection.\(^5\) The stock cultures were maintained (~70°C) in 50% glycerol. For experimental inoculations, cultures of _L. monocytogenes_ were grown on brain heart infusion agar plates seeded with 0.1 mL of each serial 10-fold dilution (30°C for 24 h, in 5% O\(_2\), 10% CO\(_2\), 85% N\(_2\)).

**Dietary Vitamin E**

DL-α-Tocopherol acetate (500 IU/g Rovimix E-50%),\(^4\) was used in the corn-soybean meal-based diet formulation, as described by Nam et al. (2003).

**Turkeys**

**Experiment 1.** One-day-old mixed sex Large White turkeys (n = 90) were obtained from a local hatchery and allotted to six rooms. Two rooms each (30 turkeys total) were randomly assigned to one of the three dietary treatments containing 0, 100, or 200 IU vitamin E/kg feed. After 5 wk, cloacal swabs were taken with sterile cotton-tipped applicators\(^5\) to ensure that birds were culture-negative for _Listeria_. Any turkeys positive for _Listeria_ were eliminated prior to experimental inoculation. No attempt was made to select birds, which were innately resistant to _Listeria_. One week later, only _Listeria_-negative turkeys were orally challenged with 1 mL of _L. monocytogenes_ (1 × 10\(^{8}\) cfu/mL). To monitor infection status, cloacal swabs were taken at 1, 4, 5, and 6 d post-inoculation (DPI). Turkeys (4 to 5 per group) were necropsied at 5, 8, 11, 14, and 25 DPI. Liver, spleen, cecum, duodenum, ileum, and colon from each bird were collected and processed for _Listeria_ isolation as described below.

**Experiment 2.** One-day-old mixed sex Large White turkeys (n = 70) were obtained from a local hatchery and allotted to 4 rooms. Two rooms (35 turkeys total) were randomly assigned to diets containing either 0 or 200 IU vitamin E/kg feed. Prior to infection at 5 wk, cloacal swabs were taken and cultured for _Listeria_. At 6 wk, 30 _Listeria_-negative turkeys in each diet group were orally challenged with 1 mL of _L. monocytogenes_ (1 × 10\(^{8}\) cfu/mL). The remaining five _Listeria_-negative turkeys in each diet group were moved to the clean pens and served as non-infected controls. To monitor infection status, cloacal swabs were taken at 1, 2, 3, 4, 6, 8, and 10 DPI. Turkeys (~5 per group) were necropsied at 2, 4, 6, 8, and 10 DPI. Liver, spleen, cecum, duodenum, ileum, and colon from each bird were collected and processed for _Listeria_ isolation as described below.

**Bacterial Isolation**

To culture _Listeria_, cloacal swabs were placed in UVM I (10 mL)\(^6\) and incubated (2 to 3 d, 30°C, in 5% O\(_2\), 10% CO\(_2\), and 85% N\(_2\)). After enrichment, 100-μL UVM I enrichment was transferred into 10-mL _Listeria_ secondary enrichment broth (UVM II) and incubated (30°C, in 5% O\(_2\), 10% CO\(_2\), and 85% N\(_2\)). After ~48 h, 100 μL of UVM II was plated to PALCAM _L. monocytogenes_ selective agar\(^6\) (30°C, 5% O\(_2\), 10% CO\(_2\), and 85% N\(_2\) for 48 h). At necropsy, the liver, spleen, cecum, duodenum, ileum, and colon from each bird were sampled, enriched in UVM I (10% wt/vol), and cultured as described above.
Two presumptive Listeria spp. colonies were recovered from each PALCAM agar plate and were verified as L. monocytogenes by a multiplex PCR assay as described (Wesley et al., 2002). A total of 245 isolates from cloacal swabs and viscera were stored (4°C) on tryptic soy agar slants supplemented with 0.6% yeast extract and assayed for virulence.

**Virulence Assay for L. Monocytogenes Isolates**

Single microcolonies from each of 245 Listeria isolates recovered from infected turkeys were tested in vitro for virulence, as described (Bhunia et al., 1994, 1995). The ratio of L. monocytogenes cells per each target hybridoma cell was approximately 1,000:1. Tissue culture plates were incubated (37°C and 7% CO2) for 6 h prior to scoring Ped-2E9 cell death using a trypan blue7 exclusion assay. Percent hybridoma cell death at 6 h after microcolony challenge was calculated as follows: [(L NC - L LC) / L NC] × 100, where L NC = number of total live Ped-2E9 cells observed in untreated or unchallenged control wells, and L LC = number of live Ped-2E9 cells in wells challenged with Listeria strain. Isolates that killed >70 to 90% Ped-2E9 cells within 6 h of challenge, which was comparable to the reference strains of L. monocytogenes, were scored as highly virulent. Isolates that killed <10% of Ped-2E9 cells, which was comparable to the 8 to 10.6% cell death observed for L. innocua (negative control), were scored as avirulent.

**Serum Vitamin E (α-Tocopherol) Analysis**

Blood samples (10 mL) were collected in serum separation vacutainer tubes.7 Serum vitamin E analyses were performed with a Hewlett Packard (HP) 6890 GC equipped with an on-column capillary injector and a FID detector.8 Serum vitamin E was calculated using an internal standard, 5α-cholestane, and expressed as micrograms per milliliter (Du and Ahn, 2002).

**Flow Cytometric Analysis of Lymphocyte Population**

Five milliliters of blood was collected from the wing vein into a vacutainer tube containing sodium heparin.7 The heparinized whole blood was transferred into a 15-mL conical centrifuge tube containing 5 mL of fluorescence buffer (FB is PBS containing 1% heat-inactivated fetal blood serum and 0.05% NaN3). The contents were mixed and centrifuged (200 g for 15 min, 4°C). Theuffy coat was collected, washed three times with FB, and resuspended in 0.5 mL FB, as described (Stabel et al., 2000).

Statistical Analysis

A completely randomized design with unequal numbers of subjects was used to examine the effects of L. monocytogenes recovery from cloacal swabs of infected turkeys on vitamin E supplemented (200 IU) and the control (0 IU) diets. Regression equations were fit for percentage of L. monocytogenes recovery as a function of DPI. A general linear models F-test for full and reduced models was used for comparison. If a significant test statistic was found, indicating unequal swab responses of the two diet groups, 95% confidence intervals were calculated for each group on each day to highlight where differences were occurring (Neter et al., 1990). The mean and standard deviations of serum vitamin E as well as immune cells were analyzed statistically by the general linear models procedure using SAS software.11 Student-Newman-Keuls’ multiple range test was used to compare differences among mean values (P < 0.05). Means and SEM are reported.

**RESULTS**

**Serum α-Tocopherol (Vitamin E)**

Dietary vitamin E resulted in an increase in serum α-tocopherol (vitamin E) for experiments 1 and 2 (Table 1). At the time of experimental inoculation with L. monocytogenes (wk 6), serum vitamin E levels in both the 100 IU and 200 IU vitamin E treatment groups were significantly
ZHU ET AL.1562
FIGURE 1. Comparison of the recovery of Listeria monocytogenes from cloacal swabs of turkeys fed control (0 IU) or a vitamin E (200 IU) diet. Significantly fewer turkeys harbored L. monocytogenes on d 2 and 3 post-infection (DPI) when fed vitamin E (200 IU). An asterisk (*) indicates a statistically significant difference between 0 IU (curve a) and 200 IU vitamin E (curve b) treatments at 2 and 3 DPI.

Recovery of L. monocytogenes in Cloacal Swabs

In experiments 1 and 2, pre-inoculation cloacal swabs were negative for L. monocytogenes. In experiment 1 at 1 DPI, L. monocytogenes was detected in cloacal swabs of turkeys (22/24, 91.7%) fed the control diet (0 IU vitamin E), as well as birds fed 100 IU (21/24, 87.5%) and 200 IU (17/25, 68%) vitamin E. At 4 DPI, L. monocytogenes was detected in swabs of 8.3% of control diet turkeys (2/24), whereas only one bird each was positive in the 100 IU (1/24, 4.2 %) and 200 IU (1/25, 4 %) treatment groups. On d 5 PI, three control birds (3/24, 12.5%) were positive, in contrast to none of the turkeys in the 100 IU and 200 IU groups. In experiment 2, all days of post-infection sampling, L. monocytogenes was recovered more frequently from cloacal swabs of turkeys fed the control diet (0 IU) than in turkeys fed 200 IU vitamin E. When data from the two trials were combined (Figure 1), L. monocytogenes was cultured more frequently ($P < 0.01$) on d 2 and 3 in birds receiving 200 IU vitamin E when compared to control birds (0 IU).

Recovery of L. monocytogenes in Tissues

In experiment 1, L. monocytogenes was recovered more often in the ceca and ileum of control diet turkeys versus vitamin E-treated birds at 5 DPI. L. monocytogenes was not recovered from the intestine or tissue samples of turkeys on either control of vitamin E diets after 8 DPI (data not shown). For experiment 2, as summarized in Table 2, there were fewer tissue samples positive for Listeria in vitamin E-treated birds at 2, 4, or 6 DPI. At 8 DPI, L. monocytogenes was not recovered from any group (control and vitamin E).

Virulence Assays for L. monocytogenes Isolates

A total of 240 out of 245 isolates (98%) recovered from infected turkeys and submitted for virulence testing killed >70% to 90% of target hybridoma cells within 6 h of challenge. These were scored as highly virulent as were the inoculating strain (ATCC 700301) and the reference L. monocytogenes strains (positive controls). Of these 245 isolates, 156 were recovered from cloacal swabs and the remaining 89 were from intestinal tissues of turkeys. Four remaining isolates killed 3.8 to 12.8% of Ped-2E9 cells. This finding was comparable to the 8 to 10.6% cell death observed for L. innocua (negative control). These were scored as avirulent, and later were confirmed by PCR as isolates that were not L. monocytogenes.

1Percentage of infected birds sampled for each day for each group, n = 5.
Flow Cytometric Analysis of Lymphocytes

As summarized in Figure 2, for experimentally infected birds, CD4\(^+\) populations of turkeys fed 200 IU vitamin E were increased \((P < 0.05)\) at 6, 8, 10, and 31 DPI when compared to infected turkeys fed control diets (0 IU vitamin E) (Figure 2a). At 6 and 8 DPI, the CD8\(^+\) T lymphocytes were higher \((P < 0.05)\) in infected turkeys given 200 IU vitamin E than in infected turkeys on control diets (0 IU vitamin E) (Figure 2b). CD4\(^+\)CD8\(^+\) double positive lymphocytes of experimentally infected turkeys on the 200 IU vitamin E diet were also markedly elevated \((P < 0.05)\) at 6 and 8 DPI when compared to infected birds on the control (0 IU vitamin E) diet (Figure 2c).

**DISCUSSION**

The impact of dietary vitamin E on both gut colonization as well as on CD4\(^+\) and CD8\(^+\) T lymphocyte populations was evaluated in turkeys experimentally infected with *L. monocytogenes*. The vitamin E doses used were those previously shown to improve meat quality (Ahn et al., 1997, 1998). Serum vitamin E increased proportionately with dietary vitamin E content. This reflects effective gut absorption of vitamin E by the time of experimental challenge at the sixth week of dietary treatment. When cloacal swab data for the two trials were combined, *L. monocytogenes* was cultured more frequently \((P < 0.01)\) on d 2 and 3 in birds receiving 200 IU vitamin E when compared to control birds (0 IU). Vitamin E supplement was previously reported to have increased the resistance of mice to influenza virus as well as of chickens to Newcastle disease virus, and increased antibody production and phagocytosis in chickens infected with *E. coli* (Tengerdy and Brown, 1977; Franchini et al., 1991; Han et al., 2000).

No virulence differences of *L. monocytogenes* recovered from in birds receiving vitamin E were detected using the PedE9 assay. The inoculating strains (ATCC 700301) and nearly 99% of the isolates recovered from cloacal swabs as well as from tissues, including spleen, liver, and intestine, were pathogenic for Ped-2E9 hybridoma cells after 6 h of incubation.

In order to determine the role of dietary vitamin E on immune parameters, the lymphocytes of infected turkeys were analyzed. In this current study, dietary vitamin E (200 IU) was associated with elevation of CD4\(^+\) (6, 8, and 31 DPI), CD8\(^+\), as well as CD4\(^+\)CD8\(^+\) T lymphocytes (6 and 8 DPI) in *Listeria*-infected turkeys, when compared with infected turkeys on control diets. This observation was in concert with the requirement of CD4\(^+\) and CD8\(^+\) T cells to eliminate listeriosis (Unanue, 2002).
