Angle-resolved photoemission study of the rare-earth intermetallic compounds: RNi2Ge2 (R=Eu,Gd)

Abstract
Experimental energy bands mapped from normal-emission photoelectron spectra of EuNi2Ge2 and GdNi2Ge2 surfaces show four photoemission features that disperse in both materials in good agreement with band calculations. Segments of the Fermi surfaces mapped by angle-resolved photoemission spectroscopy in the ΓXPZ plane of the Brillouin zones for both EuNi2Ge2 and GdNi2Ge2 are in good agreement with band calculations. This Fermi surface segment changes when one electron is added to EuNi2Ge2, corresponding to GdNi2Ge2, based on the rigid-band approximation.

(Received 5 April 2004; published 18 August 2004)

Experimental energy bands mapped from normal-emission photoelectron spectra of EuNi\(_2\)Ge\(_2\) and GdNi\(_2\)Ge\(_2\) (001) surfaces show four photoemission features that disperse in both materials in good agreement with band calculations. Segments of the Fermi surfaces mapped by angle-resolved photoemission spectroscopy in the \(\Gamma XPZ\) plane of the Brillouin zones for both EuNi\(_2\)Ge\(_2\) and GdNi\(_2\)Ge\(_2\) are in good agreement with band calculations. This Fermi surface segment changes when one electron is added to EuNi\(_2\)Ge\(_2\), corresponding to GdNi\(_2\)Ge\(_2\), based on the rigid-band approximation.

I. INTRODUCTION

EuNi\(_2\)Ge\(_2\) and GdNi\(_2\)Ge\(_2\) are two members of the \(RT_X\) \((R=\text{rare earth}, T=\text{transition metal, and } X=\text{Si, Ge})\) family of the ternary rare-earth intermetallic compounds, studied since the early 1980s. Extensive studies of the \(RT_X\) with their wide variety of magnetic properties can be found in Refs.\(^1\)–\(^3\). The magnetic properties of the rare-earth nickel germanides \(\text{RNi}_2\text{Ge}_2\) were recently studied in more detail.\(^4\) Their long-range magnetic order can be explained by the indirect Ruderman-Kittel-Kasuya-Yosida (RKKY) exchange interaction between the magnetic rare-earth ions through the conduction electrons.\(^5\)\(^6\)

Experimental studies of EuNi\(_2\)Ge\(_2\) and GdNi\(_2\)Ge\(_2\) polycrystalline samples, respectively, show the magnetic properties. Segments of the Fermi surfaces mapped by angle-resolved photoemission spectroscopy in the \(\Gamma XPZ\) plane of the Brillouin zones for both EuNi\(_2\)Ge\(_2\) and GdNi\(_2\)Ge\(_2\) are in good agreement with band calculations. This Fermi surface segment changes when one electron is added to EuNi\(_2\)Ge\(_2\), corresponding to GdNi\(_2\)Ge\(_2\), based on the rigid-band approximation.

II. EXPERIMENT

EuNi\(_2\)Ge\(_2\) and GdNi\(_2\)Ge\(_2\) crystallize in the ThCr\(_2\)Si\(_2\) structure (space group \(I4/mmm\), with a body-centered-tetragonal (bct) lattice. The corresponding simple tetragonal unit cell is shown in Fig. 1. The experimental lattice parameters are \(c=10.10\) Å and \(a=4.14\) Å for EuNi\(_2\)Ge\(_2\), and \(c=9.783\) Å and \(a=4.063\) Å for GdNi\(_2\)Ge\(_2\).\(^1\)\(^2\) Single crystals were grown using a high-temperature-solution-growth technique.\(^1\)\(^3\) All photoemission experiments were carried out at the Ames/Montana ERG/Seya beam-line\(^1\)\(^4\) at the Synchrotron
Radiation Center, Stoughton, Wisconsin. The samples were cleaved in situ at a pressure below \(3 \times 10^{-11}\) Torr, and temperature below 20 K. The clean surfaces were \((001)\) planes.

The overall energy resolution of the experiment, determined from the Fermi edge of a sputtered Pt foil, was about 50 meV at \(h\nu=22\) eV and 145 meV at \(h\nu=70\) eV. The analyzer input lens had an angular acceptance of 2°, about 6% of the distance from \(G\) to \(X\) in the Brillouin zone. The Fermi energy \(E_F\) of the system was calibrated from the valence-band spectrum of a freshly sputtered Pt foil in electrical and thermal contact with samples. The angle of incidence of the \(p\)-polarized photons was \(40°\) with respect to the sample surface normal. The sample alignment was determined in situ by using the symmetry of the dispersion of spectral features at high-symmetry points.

III. RESULTS AND DISCUSSION

Figure 2 shows photoelectron energy distribution curves (EDCs) for EuNi\(_2\)Ge\(_2\) taken at normal emission from an \((001)\) surface with a range of photon energies \((h\nu'\)'s). The four dispersing features are a feature around 1 eV (A), a weak feature around 1.5 eV (B), another around 2 eV (C), and a feature around 2.5 eV (D). Feature A exhibits significant energy dispersion with changing \(h\nu\) over an energy range of nearly 0.38 eV, from its deepest value of 1.28 eV binding energy (BE) at \(h\nu=48\) eV to its smallest value, 0.90 eV at \(h\nu=33\) eV. One set of peaks, labeled C, appears at an almost fixed BE of around 2 eV, independent of the incident photon energy, which shows that any dispersion is small. This is expected from \(d\)-character bands, which dominate this region of the valence band. Feature D disperses as the photon energy is changed from 14 to 26 eV, clearly showing a BE shift between 2.6 and 2.8 eV. At higher photon energies \((h\nu>30\) eV), we found small dispersion for features B and D, although the peak intensity is low. Dispersion might be masked by strong intensity modulations due to matrix-element effects if the features are composite in nature.

Figure 3 presents similar spectra for GdNi\(_2\)Ge\(_2\). There are four features which exactly correspond to those of EuNi\(_2\)Ge\(_2\), at around 1.2 eV (A), a weak feature around 1.8 eV (B), another around 2.2 eV (C), and one around 2.8 eV (D). It is notable that all features for GdNi\(_2\)Ge\(_2\) are at about 0.25 eV lower BE than those of EuNi\(_2\)Ge\(_2\). Feature A disperses from its deepest value of 1.30 eV at \(h\nu=22\) eV to its smallest value of 1.25 eV at \(h\nu=32\) eV. Feature D disperses as the photon energy is changed from 14 to 2.2 eV. Looking again at feature A in both materials, we see that it disperses at almost all photon energies. There is some symmetry as it curves towards and away from \(E_F\). This is required by crystal periodicity and can be used as a cross-check in band dispersions of complicated systems.\(^{15}\) The dispersions in Figs. 2 and 3 are strong enough that we were able to map them through \(k\) space and look for symmetry points. The high

![FIG. 1. Crystal structure of EuNi\(_2\)Ge\(_2\) and GdNi\(_2\)Ge\(_2\). Eu or Gd, Ni, and Ge atoms are represented by large filled circles, small shaded circles, and the white circles respectively.](image1)

![FIG. 2. EDCs for EuNi\(_2\)Ge\(_2\) at normal emission from the (001) surface (\(\Gamma-Z\) direction) taken with increasing photon energy. Binding energies (BEs) are referenced to the Fermi energy (\(E_F\)) and the spectra have been arbitrarily displaced along the ordinate for clarity. The vertical bars are a guide to the eye which qualitatively follow the major features of the scans.](image2)
symmetry points, $\Gamma$ and $Z$, are indicated to the right and left of feature A in Figs. 2 and 3.

Inside the crystal the electronic potential is approximated according to the muffin-tin model, i.e., spherically symmetric potentials around each atom and a constant potential in between.\[^{16}\] Assuming the free electronlike final-state model\[^{17}\] in a constant positive inner potential $V_0$, the momentum perpendicular to the surface ($k_f$), the momentum parallel to the surface is zero in normal emission, $k_f$, the momentum perpendicular to the surface (001), is to be evaluated. This approach is useful when the photon energy is above about 30 eV, so that a free-electron final state is a reasonable approximation. The work function $\Phi$ was set to $\Phi=4.3$ eV and $V_0$ is to be determined. In fact, the actual work function barrier seen by a photoelectron is the work function of the electron analyzer since the sample is in electrical contact with the energy analyzer but we assumed that it is very close to that of the sample itself. Going beyond the Z point at the zone boundary, the peak reverses its dispersion and traces its way back to the $\Gamma$ point in the next Brillouin zone. This symmetric behavior of the dispersion around $\Gamma$ and $Z$ can be used to determine the value of $V_0$ by adjusting $V_0$ to make $k_f$ fit the dispersion of repeating band feature A. The values of $V_0$ for EuNi$_2$Ge$_2$ and GdNi$_2$Ge$_2$ were estimated to be 11.0±0.2 and 11.5±0.2 eV by using a direct-transition model and assuming a free-electron band structure. They are in excellent agreement with the bottoms of the free-electron-like bands (10.95 and 11.48 eV, respectively) in the band structures in Ref. 18.

We compare the experimentally measured band dispersions of EuNi$_2$Ge$_2$ and GdNi$_2$Ge$_2$ with the theoretical band structure calculations along the $\Gamma$-$Z$ direction performed by Islam$^{18}$ in Fig. 4. A few bands were not observed because certain transitions can be forbidden by symmetry selection rules. The band dispersions of EuNi$_2$Ge$_2$ appear to be consistent with the theoretical calculations, but compared with

\[ E_{\text{kin}} = \frac{\hbar^2 k_f^2}{2m} - (V_0 + \Phi) \]  
\[ = \frac{\hbar^2 (k_{f_1}^2 + k_{f_1}^2)}{2m} - (V_0 + \Phi), \]  

where $m$ is the mass of the electron and $\Phi$ is work function of the sample and $V_0$ is referenced to $E_F$ which defines the zero of the free-electron-final-state band.

FIG. 3. EDCs for GdNi$_2$Ge$_2$ at normal emission from the (001) surface ($\Gamma$-$Z$ direction) taken with increasing photon energy from 14 to 44 eV.

FIG. 4. The measured band dispersion of (a) EuNi$_2$Ge$_2$ and (b) GdNi$_2$Ge$_2$ along the $\Gamma$-$Z$ [001] direction in comparison with the band structure calculations in Ref. 18 (full curves). Symbols show the observed direct-transition features: A (triangle), B (inverted triangle), C (diamond), and D (leftward triangle). The dotted horizontal line is the Fermi level; the solid horizontal lines are 4f bands.
the band structure calculation there is a rigid downward shift of the experimentally determined band structure. According to Ref. 18, Islam calculated the generalized electric susceptibility \( \chi_0(q) \) by shifting the \( E_F \) upward by 10 mRyd (to \( E_F' = E_F + 0.136 \) eV) for EuNi\(_2\)Ge\(_2\) and 7 mRyd (to \( E_F' = E_F + 0.095 \) eV) for GdNi\(_2\)Ge\(_2\) in order to adjust his nesting vectors. He pointed out that such a shift is not unreasonable for band calculations using the atomic-sphere approximation (ASA), when multiple bands with different orbital characters cross \( E_F \). The experimental band structure of EuNi\(_2\)Ge\(_2\) fits apparently much better with the theoretical band calculation when \( E_F \) is shifted up by \( \sim 0.136 \) eV. Therefore it seems true that it often is found necessary to shift the position of \( E_F \) within the accuracy of the electron energies, 1\% of the s, p, and d bandwidths,\(^{10}\) to align the experimental band structure with those of LMTO ASA calculations. Those of GdNi\(_2\)Ge\(_2\) are shown in Fig. 4(b) as well. But for GdNi\(_2\)Ge\(_2\), experimental photoemission data show a little better agreement with the original band structure rather than one with a Fermi level shift of 0.095 eV upward.

Theoretically, the addition of exactly “one” electron (1e/atom) was obtained from the DOS of EuNi\(_2\)Ge\(_2\) based on the rigid-band approximation. This has the effect of lifting the \( E_F \) of EuNi\(_2\)Ge\(_2\) by \( \sim 0.3 \) eV.\(^8\) Our results for GdNi\(_2\)Ge\(_2\) show that all of the observed band features have higher BEs by 0.2 to 0.3 eV compared to those of EuNi\(_2\)Ge\(_2\). Therefore the observed BE shift can be interpreted quantitatively by a rigid-band shift of \( E_F \) based on the rigid-band model as a first approximation, although a rigid-band description has been shown to be unsuccessful for some electronic states of alloys from photoemission investigations.\(^{19,20}\) Our present results are also consistent with the interpretation by Islam et al.,\(^8\) in which the \( E_F \) shift simply corresponds to an increase of one electron per rare-earth atom upon going from EuNi\(_2\)Ge\(_2\) to GdNi\(_2\)Ge\(_2\). In fact, the lattice parameters of EuNi\(_2\)Ge\(_2\) are 3\% larger than those of GdNi\(_2\)Ge\(_2\) due to the larger ionic radius of divalent Eu but it is assumed that it does not affect rigid-band filling much. Ignoring the difference of lattice parameters in both materials was previously supported by Islam,\(^8\) who repeated generalized susceptibility \( \chi_0(q) \) calculations by swapping the lattice constants between two compounds and found no significant changes. In the electronic band calculation, the Eu 4f and Gd 4f electrons were treated as part of the atomic cores and it is assumed that their paramagnetic bands will be similar to those of EuNi\(_2\)Ge\(_2\) and GdNi\(_2\)Ge\(_2\). Therefore the bct BZ is used in the analysis of the photoemission spectra rather than those corresponding to the perfect AF state. From our results it is also justified that the Eu 4f and Gd 4f electrons can be treated as core electrons in the band calculations.

Figure 5 shows the BZ of the bct structure with symmetry points labeled. The ΓXPZ plane on which we performed ARPES is shown hatched with the photoelectron emission angle \( \theta \) indicated. The \( k_0 \) component of the photoelectrons is along the[110] direction, as shown.

Figure 6 shows a set of angle-resolved EDCs from EuNi\(_2\)Ge\(_2\) taken with \( h\nu \)s of (a) 24 eV and (b) 29 eV from an (001) surface while changing the angle in the[110] direction (in the ΓXPZ plane). The photoelectron-emission angles relative to the surface normal \( \theta \) are marked next to each curve. All features show, upon decreasing the collection angle, a peak that sharpens somewhat upon approaching \( E_F \), then drops as the initial states cross \( E_F \). Since photoemission only measures occupied electronic states, this signifies that the initial state passed through \( E_F \).\(^{21,22}\) It can be seen that all bands disperse toward \( E_F \) on going from higher to lower angles as indicated in Figs. 6(a) and 6(b). From Fig. 6, the \( E_F \) crossing is at 20° for \( h\nu = 24 \) eV and 18° for \( h\nu = 29 \) eV. Each gives a point in a BZ lying on a FS.

Similar angle-resolved EDCs from GdNi\(_2\)Ge\(_2\) taken with each photon energy from an (001) surface at \( k \) points in the ΓXPZ plane are shown in Fig. 7. The dispersing peak of Fig. 6 is not evident, even in plots of energy derivatives of the smoothed spectra. This was the best of several surfaces measured, but it was not as good as that of EuNi\(_2\)Ge\(_2\). In order to map part of the Fermi surface of GdNi\(_2\)Ge\(_2\) we plotted the step height at the Fermi edge vs collection angle for each photon energy. For EuNi\(_2\)Ge\(_2\) there was a drop-off of about 20\% at the same angles at which the dispersing peak was judged to be crossing the Fermi level. For GdNi\(_2\)Ge\(_2\) the drop-offs were smaller, about 8\%, except at 30 eV. At this energy the fall-off was either at the largest angle used, or a still larger angle, so only a lower limit to \( k_{\phi} \) at \( E_F \) can be obtained. These results were unchanged when the normalization point in the spectra was changed.

Figure 8 shows cuts through the extended BZs of EuNi\(_2\)Ge\(_2\), GdNi\(_2\)Ge\(_2\), and the location of the FS crossing at different points mapped onto the ΓXPZ plane. The vertical axis is \( k_\perp \) relative to the (001) surface. The horizontal axis \( k_{\phi} \)
is the momentum parallel to the [110] direction. If an electron of \( E_{\text{kin}} \) with a fixed \( \theta \) from the surface normal is detected, the location of the internal final-state wave vector \( \mathbf{k}_f \) is restricted to a certain circle in \( k \) space. As the electron analyzer angle is varied at a fixed photon energy, a circular \( k \)-space arc is traversed.\(^{23,24} \) As shown in Fig. 8(a) the circular paths, composed of dots in the \( \Gamma X P Z \) plane of the BZ of EuNi\(_2\)Ge\(_2\) for \( V_0 \approx 11.0 \) eV, are contours for various constant photon energies for initial states near \( E_F \), assuming free-electron final states. The filled circles represent \( E_F \) crossing points, each determined from one set of curves. They are part of the hole surface around \( \Gamma \) in the BZ, indicating that the occupied electronic states are in the right-hand part of the \( \Gamma X P Z \) plane of EuNi\(_2\)Ge\(_2\). We see then that the FS forms an open orbit along the \( c \) axis. The curved line is from the band calculation from Ref. 18. In fact, two bands cross along \( \Gamma - X \) but only the band crossing nearest to \( X \) is observed. There is a close correspondence of the theoretical and experimental FS.

The locations of the \( E_F \) crossings at different points mapped onto the \( \Gamma X P Z \) plane of GdNi\(_2\)Ge\(_2\) are shown in Fig. 8(b). Again, the right-hand part of the \( \Gamma X P Z \) plane of GdNi\(_2\)Ge\(_2\) contains the occupied electronic states. Compared to the FS of EuNi\(_2\)Ge\(_2\), that of GdNi\(_2\)Ge\(_2\) has a bulge toward the \( \Gamma \) point, due to the extra conduction electron from the Gd\(^{3+} \) ion, confirming again the effects of rigid-band filling on electronic structures together with the previous data on the energy band mappings. Thus a simple rigid-band model offers a way to estimate the amount of \( E_F \) variation, corresponding to an increase of exactly \( 1 \) electron in EuNi\(_2\)Ge\(_2\), upon going from EuNi\(_2\)Ge\(_2\) to GdNi\(_2\)Ge\(_2\). One future experiment might be to do ARPES on Gd\(_{1-x}\)Eu\(_x\)Ni\(_2\)Ge\(_2\) pseudoternary alloys to study gradual band-filling effects in detail. Changing the stoichiometry of these pseudoternary alloys would permit observation of gradual changes in the FSs and the evolution of the electronic band structure with increasing Gd concentration.

IV. CONCLUSIONS

The electronic structures of EuNi\(_2\)Ge\(_2\) and GdNi\(_2\)Ge\(_2\) have been investigated using photoemission spectroscopy, via energy bands mapped from the normal-emission spectra of EuNi\(_2\)Ge\(_2\) and GdNi\(_2\)Ge\(_2\)(001) surfaces. Four major photoemission features dispersing along the normal [001] BZ direction in both materials are in good agreement with earlier band calculations. Our results for GdNi\(_2\)Ge\(_2\) show that all of the observed band features are shifted downward by 0.2 to 0.3 eV compared to those of EuNi\(_2\)Ge\(_2\), corresponding to an increase of one electron \((1 e/\text{atom})\) in GdNi\(_2\)Ge\(_2\) upon going from EuNi\(_2\)Ge\(_2\) to GdNi\(_2\)Ge\(_2\). The FSs mapped by ARPES in the \( \Gamma X P Z \) planes of the BZs for both materials were in good agreement with those from band structure calculations. EuNi\(_2\)Ge\(_2\) is isostructural to GdNi\(_2\)Ge\(_2\), but its conduction band has one less electron. Compared to the FSs of EuNi\(_2\)Ge\(_2\) in the \( \Gamma X P Z \) plane of the BZ, GdNi\(_2\)Ge\(_2\) has a bulge toward the \( \Gamma \) point, indicating that \( E_F \) is located at a higher energy than that of EuNi\(_2\)Ge\(_2\). It can also be said that the FS will shrink toward the \( X \) point in the \( \Gamma X P Z \) planes when electrons are removed in GdNi\(_2\)Ge\(_2\). Therefore those compounds which give the same Hund’s rule ground state \((S_{7/2})\) were an ideal system for the study of effects of band filling on electronic structures.
FIG. 7. The angle-resolved EDCs from GdNi$_2$Ge$_2$ taken with photon energies of (a) 20 eV and (b) 22 eV from a (001) surface at $k$ points in the ΓXZ plane. ($\theta$ is the emission angle from the sample normal.) Vertical bars following the features are included to help guide the eye.

FIG. 8. Fermi surfaces (FSs) mapped in the ΓXZ plane of (a) EuNi$_2$Ge$_2$ and (b) GdNi$_2$Ge$_2$ using an extended zone scheme. Dotted circular arcs through the BZ relate $k_j$ to $k_f$ at constant photon energy for initial states near $E_F$. The $k$ locations for observable transitions at fixed collection angles are along the paths marked with crosses. Filled circles indicate the experimental data. The solid line indicates the theoretical FS of EuNi$_2$Ge$_2$ and GdNi$_2$Ge$_2$ by Ref. 18.
